Royal Society, February 4.—**W. A. Bone** and **R. Quarendon**: Researches on the chemistry of coal Pt iv. The "residues" obtained after the extraction of coals with benzene under high pressure can be easily oxidised by alkaline solutions of potassium permanganate, yielding a complex mixture of benzenoid carboxylic acids amounting to between 25 and 40 per cent. of the weight of the "coal-residue" treated. These acids include 1, 2, 3, 4 *benzene tetracarboxylic* acid and mellitic (*benzene hexacarboxylic*) acid —**G M B. Dobson** and **D N. Harrison**: Measurements of the amount of ozone in the earth's atmosphere and its relation to other geophysical conditions. Measurements of the amount of ozone in the atmosphere were made almost daily throughout 1925, and a few measurements were also taken during the autumn of 1924. The average amount is about 0·3 cm, which agrees with former measurements A marked connexion is found between the atmospheric pressure and amount of ozone, the latter being large in cyclonic and small in anti-cyclonic conditions. There is a well-marked annual period with a maximum in spring and minimum in late autumn. The probable error of observation is about 0·005 cm of ozone.—**C. Chree**: Atmospheric ozone and terrestrial magnetism. Using the results of the paper above, there appears to be a decided association of magnetic disturbance and higher values of ozone. Owing to the tendency to sequences of high ozone figures and of days of magnetic disturbance, it is difficult to say exactly how synchronous the phenomena are. The figures suggest that the high ozone figure precedes the crest of magnetic disturbance —**J. S Owens**: Condensation of water from the air upon hygroscopic crystals Deliquescence of crystals of pure salts depends upon the vapour pressure of their saturated solutions, while mixed salts, as found in air, behave in a different manner from pure salts. It is usually assumed that before fog can be formed the air must be saturated, or nearly so; but it is demonstrated that all the examples of crystals obtained from the air would become liquid in air very much under-saturated Thus the crystals from Algarve (Portugal) collected water at 69 per cent. relative humidity at 56° F; crystals from the neighbourhood of the mouth of the St Lawrence deliquesced at about 77 per cent relative humidity at 56° F. Crystals obtained in Bournemouth deliquesced at about 67 per cent relative humidity at 62° F, indicating that it is not necessary for air charged with such crystals even to be near saturation for a fog of liquid drops to form —**T. H. Havelock**: Wave resistance. some cases of unsymmetrical forms. The type of asymmetry is suggested by the general effect of fluid friction in reducing the wave-generating properties of the rear portion of the model. Pairs of models are examined in which one model is symmetrical fore and aft, while in the other the rear portion is curved off into more of a streamline form This produces a marked decrease in the magnitude of the interference phenomena.—**H. Jeffreys**: On the formation of water waves by wind. On the hypothesis that, in a first approximation, water waves may be considered irrotational, viscosity and other factors tending to change the amplitude being small, the conditions of growth of waves under the action of wind, even when the depth is finite and surface tension is allowed for, have been investigated. The rate of decay of waves, in the absence of wind, is independent of the depth and the surface tension. The easiest waves for a wind to raise are always two-dimensional, and are gravity waves, not ripples The wind velocity needed to produce waves is greater in shallow water than in deep water. The longer waves on shallow water (less than about 1 cm deep) are, however, so much affected by viscosity that the hypothesis is invalid for them; it seems they can in no case be formed by wind The waves produced on shallow water must therefore be very short, about 2-3 cm. say, which agrees with observation.—G. T **Morgan**, W. J. **Hickinbottom**, and T. V. **Barker**: Stereoisomeric diaryl-*β*-*γ*-diamino-*n*-butanes The secondary diamines of the general type $Ar.NH.CH(CH_3).CH(CH_3).NH.Ar$ contain two asymmetric carbon atoms, either mirror images of each other or absolutely identical. Like tartaric acids these bases should exist in an internally compensated *meso*-form, as well as an externally compensated mixture, potentially resolvable into optically active modifications The most fully investigated series of compounds are those containing the *p*-tolyl residue:

$$CH_3.C_6H_4\ NH.CH(CH_3).CH(CH_3).NH.C_6H_4.CH_3,$$

and the study of these bases affords a highly satisfactory confirmation of the requirements of stereochemical theory —G. T. **Morgan** and G. R. **Davies**: Antimonial analogues of the cacodyl series Methyl arsenicals were first discovered by Louis Claude Cadet de Gassicourt in 1760 (*Paris, Acad., Sci. Mém. Div. Sav.* t. 3, p. 623). Similar experiments on organic compounds of antimony led to the preparation of tertiary stibine and other derivatives by Lowig and Schweizer and by Landolt, but the antimonial analogues of the cacodyl series have so far eluded isolation. The thermal decomposition of trimethylstibine dihalides has now been investigated, the following reaction having been generalised when X is chlorine, bromine, or iodine.

$$(CH_3)_3SbX_2 = (CH_3)_2SbX + CH_3X.$$

This process affords the means of proceeding from the tertiary to the secondary series of organic antimonials.—G. T. **Morgan** and V. E **Yarsley**: Dimethylstibine cyanide, an analogue of cacodyl cyanide. When anhydrous reagents are used, cyanogen bromide combines readily with trimethylstibine dissolved in light petroleum to form trimethylstibine cyanobromide, a white crystalline compound. This is relatively stable, and is only decomposed *in vacuo* at high temperatures, when dimethylstibine cyanide is obtained as a colourless crystalline compound, m p. 113°-114°. This cyanide, the analogue of Bunsen's cacodyl cyanide, fumes on exposure to air, with the formation of white infusible trimethylstibine oxycyanide.

Faraday Society, January 18 —B. B. **Banerji**: The electrode capacity and resistance of electrolytes for a wide range of frequencies. The laws of variation suggested by Haworth and by Warburg are satisfied only through small ranges of frequency; a law is given which holds throughout the range investigated. The hypothesis of double leaky capacities at the electrodes has been put forward to explain this law. The existence of the capacities is ascribed, one to the double layer and another to the concentration changes brought about by the transport phenomena. The thickness of the double layer calculated from the value of the double-layer capacity is of the proper order and consistent with the value found by other methods.—J. A. V. **Butler**, W. E. **Hugh**, and D. H. **Hey**: A note on the effect of the electrode material on oxidation potentials. The independence of oxidation potentials of the electrode material, when this takes no appreciable part in the cell reaction, is confirmed.—R. E. W. **Maddison**: The electromotive behaviour of cupric oxide. (1) The behaviour of the electrode Pt/Cu_2O, CuO, N-NaOH has been re-examined Initially, it gives a relatively positive P.D, which gradually becomes more negative The initial and final P D's depend on the temperature of preparation of the oxide, and on the duration and method of heating.—A. **Highfield**: The colloidal properties of nitrocellulose sols in mixed solvents. Nitrocellulose and its solvents contain both strongly and weakly polar groups Mixed liquids are solvents if they contain these two classes of groups balanced in suitable proportions, and this conclusion holds whether the ingredients of the mixtures are solvents or not. The relation between the composition of solvent or solute and the viscosity of nitrocellulose sols has been investigated, and the results are in line with the conclusions reached from solubility considerations.—E. P. **Perman** and T. **Lovett**. (1) Vapour pressure of concentrated aqueous solutions of urea. These are given at the temperatures 40·02°, 60·28°, 70·39°, and 80·1° C., and the densities up to a concentration corresponding very nearly with saturation are given at the same temperatures. Van Babo's law does not hold for aqueous solutions of urea. The results indicate a normal molecular weight and no hydration for urea in aqueous solution. (2) The heats of dilution of concentrated solutions of urea at various temperatures. An original method is described by which these can be measured From the results obtained it is possible to obtain the heat of dilution as defined by Kirchhoff's equation, the total heat of dilution between any two concentrations, and the relation between the heat of dilution and the concentration. A new method of determining solubilities is suggested —W. **Taylor**: A note on kinetic activation as a factor in gas reactions.

CAMBRIDGE.

Philosophical Society, January 18.—H. F **Baker**: On chains of two-two relations, and the theory of elliptic functions —G. C **Stewart**: The aberrations of a symmetrical optical system. The geometrical aberrations are considered in detail for the first three orders—both for the paraxial image plane and also for out-of-focus planes. Aberrations of all orders fall severally into one or other of two general types.—W. **Burnside**: On a group of 1440 birational transformations of four variables that arises in considering the projective equivalence of double sixes —P. L. **Kapitza**: Over-tensions in a condenser battery during a sudden discharge. If a large condenser battery made of Leyden jars is discharged through a small self-induction, the tension across the jars reaches sometimes very large values, which may break the insulation across the Leyden jars. A photograph of the spark in this case shows that the current from the jars goes through the main circuit only for a few half periods. Due to the self-induction of the connecting wires, oscillations are produced in the battery between the Leyden jars, which account for the over-tension.—H. S **Hirst**. Photocatalysis at mercury surfaces. A mercury surface, irradiated by ultra-violet light strong in the line $\lambda = 2536 \cdot 7$ Å U., exerts a catalytic influence on the photochemical union of hydrogen with gases such as oxygen, ethylene, and carbon monoxide. The velocity of reaction is to the first order proportional to the area of surface exposed. A film of mercuric oxide on the mercury forms only in the presence of both hydrogen and oxygen. In the combination of nitrogen and hydrogen, hydrazine and ammonia have been identified, and in the case of oxygen and hydrogen, hydrogen peroxide and water. It is suggested the reactions proceed by steps The catalytic efficiency of the surface depends on its cleanness and is cut down by poisons —P. **Bracelin**. The period of decay of RaB and RaC Measurements of the saturation currents produced between two parallel plates by a source of radium C give a transformation constant of $(3 \cdot 514 \pm 0 \cdot 007) \times 10^{-2}$ min $^{-1}$ for radium C, corresponding to a half value period of $19 \cdot 72 \pm 0 \cdot 04$ minutes Similar measurements have been made on sources of radium active deposit and the decay compared with the values calculated by assuming the above period for radium C and trying various values for that of radium B. The experimental results indicate a value between 26·7 to 26·8 minutes

EDINBURGH.

Royal Society, January 25 —T **J. Jehu** and **R. M. Craig** Geology of the Hebrides Pt iii North Uist and Benbecula The outstanding feature is the belt of crushed and sheared rocks traceable along the eastern side of Benbecula and North Uist, and separated by a thrust-plane from the relatively undisturbed gneisses forming the western and greater part of the area. This forms a continuation of that along the eastern side of South Uist It is made up of crushed gneisses, mylonites, and flinty crush material intermixed, in contrast to the definite zones traceable in the case of South Uist The dominant gneisses of the western area are acid biotite-gneiss, hornblende-biotite-gneiss, hornblende-gneiss, and garnetiferous hornblende-gneiss. Pyroxene and hornblende granulites often, rich in garnets are intrusive into the dominant gneisses Bands of pegmatite are frequent, sometimes yielding good graphic granite. Ultra-basic rocks in bands converted into actinolite schists occur especially in the isles of Berneray and Pabbay. All these types are altered igneous rocks of the Archæan complex Minor intrusions of Tertiary age are much less frequent than in the more southern isles The three Maddys, rocky islets at the entrance to Loch Maddy, are portions of an olivine-dolerite sill. Evidences of recent subsistence are afforded by submarine peat off the coast and by the drowning of fresh-water lochs.—T. M **Finlay**: The Old Red Sandstone of Shetland A new fossil zone occurred a short distance below the conglomerate in the south-eastern area of the Old Red Sandstone This has yielded three species of fish, *Dipterus valenciennesi*, Microbrachius sp nov., and a new genus *Stegotrachelus finlayi*, a palæoniscid of extreme interest as being the earliest of the family known in complete specimens from the Devonian, and the first to be recorded from the Old Red Sandstone of Europe The genus has been described and figured by Smith Woodward and White —J. Kaye **Charlesworth**. (1) The glacial geology of the southern uplands of Scotland, west of Annandale and Upper Clydesdale The lines of ice-flow over the region by striæ, drumlins, and erratics has been traced and the position of the ice-edge ascertained at five successive periods of the retreat by the correlation of the moraines associated with the major glaciers. There is evidence of re-advances in connexion with two of these stages. (2) The great re-advance kame-moraines of the south of Scotland and some later stages of retreat There is an important line of re-advance of the ice around the coastal areas of north-east Ireland from the mouth of Lough Foyle to the head of Belfast Lough, by the Bride Hills of the Isle of Man and the Cumberland coast. A later position of the ice-margin is from St Abb's Head along the northern slopes of the Lammermuir and Moorfoot Hills, by Muirkirk and to the east of New Cumnock, and again at Stranraer and in the Rhinns of Galloway. At this stage, corrie glaciers lingered in the Lammermuir Hills, the Tweed below Broughton was ice-free, and the highland ice was confluent over south Ayrshire with the southern upland glaciers of (1) The North Ireland moraine is correlated with the Baltic moraine of N Germany, the later moraines with the Ra moraines of Scandinavia and the "post-glacial stages" of the Alps —A. E. M **Geddes**. Distribution of electric force in high-voltage discharges. An investigation by F. W Aston proved that for electric discharges in vacuum tubes, the potential across the dark space is equal to that across the tube, with voltages less than 1000 volts. It is now shown that, with voltages more than 13,750 volts, only a part of the total voltage is confined to the dark space, about 0·25 of the excess of the total voltage, more than 13,750 being found in the negative glow

PARIS

Academy of Sciences, December 28 —**Charles Richet, Gardner, and Goodbody**: The effects of salts of zirconium, titanium, and manganese on nutrition These metals were administered to dogs as citrates mixed with the food. Neither zirconium, titanium, nor manganese had any toxic effect Titanium and zirconium, especially the latter, appeared to have a slightly favourable effect on nutrition. The results with manganese were irregular —**Léon Guillet** The tempering of light aluminium-copper alloys containing more than 5 per cent of copper.—**Ch. Depéret** and **J Savornin**: The discovery of a fauna of Albian vertebrates at Timimoun (Western Sahara) —**E. Mathias**: Contribution to the study of fulminating materials The colour. Chemical heterogeneities The theory of ball lightning —**G. A Boulenger**: Remarks on the importance attached to the mode of insertion of the carpels for the classification of the species of the genus Rosa —**L Cuénot** The signification of homochromy in some marine animals —**Gaston Julia**. The series of rational repeated functions —**A. Zygmund**: The summation of trigonometrical series and those of powers by typical means —**A Bloch** Some theorems on integral and meromorph functions of a variable —**R. Gosse**. The equation of the deformation of surfaces —**J Cayrel** The properties of lead dioxide as a detector Lead dioxide, in combination with points of various metals (magnesium, zinc, tin, aluminium), can be used as a detector in wireless telephony.—**E Fromy** The relation between the Wiedemann effect and the Joule effect —**A. Dauvillier**: The biological action of X-rays of various wave-lengths. A discussion of the correct interpretation of some recent measurements of A Dognon. It is concluded that the large difference found by Dognon in the biological action was not justified by the experiments and that in reality the radiations $\lambda = 0 \cdot 22$ and $\lambda = 0 \cdot 7$, for equal energy absorbed, have the same biological action.—**Jean Rey** The brilliance and luminous flux of carbons of high light intensity, for projection of electric light The electric light carbons contain a central core of rare earths (salts of cerium or titanium). The illuminating power per square millimetre is very high, but falls far short of the figures claimed by the manufacturers —**Mme. J. S Lattès** and **Georges Fournier**: The absorption of the β-rays by matter —**E Darmois**. A case of mutarotation. Application to the study of the saponification of ethyl oxalate by water or dilute acids —**R de Mallemann**: The calculation of Verdet's constant in the molecular theory —**René Dubrisay** Some phenomena of capillary chemistry. Benzene solutions of fatty acids (palmitic, oleic, stearic) were allowed to run from a burette into water or weak soda solutions at different temperatures The variations in the surface tension were deduced from the size of the drop.—Charles **Grard**: The influence of the thermal zone of work on the selection of steels for the valves of aviation motors. A study of the properties of chrome-silicon steels. A steel of the type carbon 0·4 per cent, silicon 2·5 per cent, chromium 12 per cent. gave the best results on these tests, and a trial of this alloy on a 450 H.P. engine gave very satisfactory results.—Raymond **Delaby** and Maurice Marie **Janot**: Cyclohexylglycerol.—G **Georgalas** and N **Liatsikas** The new eruption of the Santorin volcano (1925). A detailed account of the phenomena observed between August 23 and October 13.—P. **Lasareff**: The results of geophysical work in the domain of the magnetic anomaly of Koursk. The magnetic anomaly is shown to be due to large deposits of iron ores The quantity of iron, calculated as metal in this region, is of the order of 2×10^{10} tons.—Rafael de **Buen**. The genesis of the Rias.—Henry **Hubert**. The evolution of very extended masses of cumulo-nimbus in Western Africa.—P. **Allorge**: The variations of the hydrogen ion concentration in some Sphagnum peats in the centre and west of France. For the peats examined the *p*H values were found to be between 3·9 and 6·8.—A. **Maige**: The unilocular or plurilocular amylogen reaction of the plasts.—André **Dauphiné**: Experimental demonstration of the vascular ratio between the leaf and the root. It was shown by G Chauveaud in 1921 that the appearance of new leaves is accompanied by the differentiation of new conducting elements in the stem and root. This is confirmed by experiments described by the author in which lesions resulting in the suppression of certain leaves correspond in the root to the absence of vascular groups.—R **Morquer**: The biology of *Mucidula mucida*.—Raymond **Hamet**: A type of medullary cribo-vascular formations new for the family of the Crassulaceæ.—M. **Mascré**: The staminal periplasmodium of the Commelinaceæ.—M. **Bridel** and C. **Charaux**: The biological method of research, in plants, on glucosides hydrolysable by rhamnodiastase. The ferment rhamnodiastase, extracted from various species of Rhamnus, causes a partial hydrolysis of glucosides, some of the molecules of glucose remaining combined together in the form of complex glucides (primeverose, rutinose, rhamninose, etc.) Results are given of the application of this ferment to various plants.—H. **Colin** and A. **Grandsire**: The chemical characters of green leaves, yellow leaves, and red leaves. Compared with normal green leaves, red autumn leaves are richer in sugars and in free organic acids, are less mineralised, and are partially decalcified. The yellow leaves are poor in sugar, but rich in water and mineral salts.—Michel **Durand**: The influence of light on the formation of tannins.—Léon **Bertin** and Fernand **Angel**. The plankton and planktonic food of the fishes of the Lake of Geneva.—Ch **Hollande**: The urate cells of acridian Orthoptera and the genesis of these urates.—Emile F. **Terroine** and Mlle. Anne Marie **Mendler**: The influence of the addition of ternary food substances to milk on the magnitude of the nitrogen retention in the course of growth. The results of experiments on the growth of sucking pigs fed with skimmed milk, whole milk, the latter alone or mixed with additional fatty or starchy material. The addition of fat or of carbohydrates to the milk caused a marked improvement in the proportion of proteid retained and utilised by the animal. Whole milk did not prove to be the ideal food.—Mme. L. **Randoin** and Mlle. A. **Michaux**: Glycogen reserves and arterial glycæmia (effective and proteidic) in the course of experimental scurvy.—Marcel **Francois**, I. **Meyerson**, and Henri **Pieron**: The latent time of reactions of equilibration to sudden longitudinal accelerations.—H. **Barthélémy**: The action of saline and aqueous extracts of eggs of the same species on the spermatozoids of *Rana fusca*.—P H. **Fischer**: The influence of light and of the renewal of air on the awakening of snails (after hibernation). The humidity of the air is not a necessary condition of the awakening of snails This is accelerated by light and by renewal of air.—F **Vlès** and A. de **Coulon**: The physico-chemical properties of certain constituents of serum.—Jivoin **Georgévitch**: The structure of the spore of *Pleistophora periplanetæ*.—Raoul **Bayeux**: Hæmatolysis and hæmatopoiasis at very high altitudes and in air experimentally rarefied. Breathing rarefied air determines a toxic hæmolysis the clinical result of which is mountain sickness It is possible that at medium heights (3000 feet) the blood may be purified by the destruction of fragile or unhealthy red corpuscles, replacing them by fresh healthy corpuscles.—Stefan **Jellinek**: Electrical accidents and artificial respiration. The author insists on the importance of immediate and prolonged artificial respiration in cases of the victims of electric shock.— — **d'Arsonval**: Remarks on the preceding communication. The views of M. Jellinek are in complete agreement with those published by the author so far back as 1885. A victim of electric shock should be treated like a person apparently drowned. As regards the method of artificial respiration, the best is that of Schaefer, possibly combined with oxygen inhalation

January 4.—H. **Deslandres**: Obituary notice of Hildebrand Hildebrandsson.—A. **Cotton** and R. **Descamps**: A photographic spectro-polarimeter for the ultra-violet. The instrument described is based on the principle that the movement of rotation of the analyser produces a displacement of the image recorded on the sensitised plate.—Julien **Costantin** and Joseph **Magrou**: Contribution to the study of the roots of alpine plants and their mycorhiza.—C. **Camichel**, L. **Escande**, and M. **Ricaud**: The determination of velocities in liquids and the paradox of Du Buat. A method of applying the Pitot tube in which, instead of measuring the difference of pressure, a compensating pressure is set up by means of a rotatory pump. Velocities of the order of 5 cm. per second can be measured.—E. **Mathias**: Contribution to the study of fulminating material The black and white globes without light of their own A development of a theory of globular lightning.—Maurice **Gevrey**: The resolution of the problems at the limits without Green's functions.— — **Mandelbrojt**: Some generalisations of theorems on series which admit of interruptions.—E. F **Collingwood**: A theorem of M. Valiron.—Julius **Wolff**: The iteration of holomorph functions in a region, the values of which belong to that region.—R. **Chambaud**. The internal potential in thick circular arches and the idea of average slipping deduced from it.—E G **Barrillon**. Concerning the part of the resistance to towing of a float due to the formation of a field of waves.—V. **Bjerknes**: The temperature of sunspots.—Th. **Vautier**: The propagation of short sound waves and of low pressure.—F. **Holweck**: The critical potential K of neon This was found to be 862 volts.—Jean **Thibaud**: The determination in absolute measure of the wave-lengths of X-rays by means of a reflection grating traced on glass. The spectroscopy of the X-rays is based on the diffraction of these radiations in crystallised media which act as gratings, of which the constant, the reticular distance *d*, can be calculated from certain hypotheses due to Bragg. The author describes experiments with a glass diffraction grating ruled with 200 lines to the millimetre and gives a reproduction of one of the spectra obtained The wave-length for the copper line $K\alpha$ was thus found to be 1·540 Å.U., in good agreement with the 1·538 Å.U. given by the crystal method.—Pierre **Sève**: A spectrograph with a non-inclined plate.—P. Mondain **Monval**: The thermal properties of viscous sulphur. The experimental results are summarised in a diagram in which the quantities of heat given out on cooling are plotted against the temperatures to which the sulphur has been heated. The curve is discontinuous, with four branches corresponding to orthorhombic, monoclinic, liquid, and viscous sulphur. The transformation of liquid sulphur into viscous sulphur at 160° C. is accompanied by an absorption of 2·8 calories per gram.—F. **Taradoire**: The rapid oxidation of drying oils and antioxygens.—L. **Bert** and P. Ch. **Dorier**: A complete synthesis of thymol starting from isopropyl alcohol. A diagram is given of the fifteen steps in this synthesis, together with the yield of each successive operation.—G. **Hugel**: Heterocyclic combinations containing pentavalent iodine or bromine.—**Orekhoff** and **Tiffeneau**: The transposition of trisubstituted aldehydes into disubstituted ketones. Details of transpositions of the type RRR′.C.CHO→RR.CH.CO.R′.—Joseph **Péneau**: The presence of Clymenia and the extension of the upper Devonian in the south-east of the Armorican massif.—E. A. **Martel**: The Bertarelli abyss (Istria), 430 metres deep.—Const. A. **Kténas**: The enclosures and ashes of Fouqué Kameni.—R. **Bureau**: The prediction of the weather and the daily variation of atmospherics.—P. **Lavialle**: The development of the anther and pollen in *Knautia arvensis*.—Pierre **Dangeard**: The flora of the peridineans of the western Channel.—G. **Nicolas**: A new and certain example of parasitism in Hepatica (*Marchantia polymorpha*).—Louis **Daniel**: Heredity of the property of second flowering in grafted plants.—Jacques **Pellegrin**: The biology of the omble trout of the Middle Atlas (*Salmo Pallaryi*).—André **Migot** and Adolf **Portmann**: *Chondranthus denudatum*, a new species from the Mediterranean.—Auguste **Lumière** and Henri **Couturier**: The toxicity of serum put in contact with starch. Serum from the guinea-pig, digested with rice starch at 37° C. and centrifuged, causes death by anaphylactic shock when injected into an animal of the same species. It was found, however, that the symptoms were attenuated when the centrifugation was prolonged for half-an-hour, and if the serum is centrifuged (tangential velocity 96 metres per second) for 50 minutes, the serum becomes completely innocuous. The author points out the bearing of these experiments on his theory of anaphylaxis, according to which the toxic agent is in all cases a flocculate more or less visible, which is insoluble and acts by its physical properties.—Jean **Roche**: The action of temperature on respiration *in vitro* of the tissues of homeotherms and poecilotherms.—Mme. L. **Randoin**, Mlles **Asselin** and **Charles**: Reproduction, growth, and food equilibrium.—Marcel **Duval** and Marcel **Prenant**: The molecular concentration of the internal medium of *Ascidia mentula*. Contrary to what has been observed with other marine invertebrates, the blood of this Ascidian is not isotonic with sea water, but is sensibly hypertonic, the difference between the freezing points of the two media being 0°·10. The proportion of chlorine in the blood is higher than that in the surrounding sea water.—J. E. **Abelous** and L. C. **Soula**: The cholesterogenic function of the spleen; the influence of the internal secretion of the spleen on cholesterogenesis in the muscles.—Edouard **Chatton** and André **Lwoff**: The structure and the evolutive cycle of the Infusoria of the cast skins of Crustacea and their place amongst the Fœttingeriideæ.—Jivoin **rgévitch**: The evolutive cycle of *Pleistophora iplanetæ*.

Racial Purification.

THE need for a radical change in the official attitude towards research into the causes of mental disorder has already been advanced in these columns. The problem afforded by the presence among us of a large number of persons suffering from congenital defects of varying severity, though allied and at some points inseparable from the problem of lunacy, has important differences. The hereditary factor is more obvious in cases of congenital mental deficiency than in most of the acquired conditions leading to certification under the Lunacy Acts. In 1923, Dr. Henry Brackenbury, writing in the *Eugenics Review*, acknowledged that "left to itself this sore of society shows no tendency towards cure. On the contrary, it becomes more accentuated generation by generation. Feeble-minded persons are more fecund than the normal; they have a tendency to mate together, and so to produce offspring markedly partaking of the parental characteristics." On January 20, 1926, with other signatories to a letter to the *Times*, the same writer said:

> "It is an undoubted fact that although the majority of cases of mental defect are the result of inheritance, the proportion of cases who are the offspring of actually defective parents is, in relation to the whole, an extremely small one."

It is conceivable that these statements are reconcilable; but while we have at least one analysis by modern statistical methods to fall back upon, it seems only fair to adopt it. Only last autumn, the Galton Laboratory published conclusions based on statistical facts relating to children of British and alien parentage, including very dull and mentally defective subjects:

> "For the practical purposes of prognosis there does not exist in the present material any correlation of the slightest consequence between the intelligence of the child and its physique, its health, its parents' care, or the economic and sanitary conditions of its home. . . . As the result of the investigations published in this paper, and in others from the Galton Laboratory, intelligence as distinct from mere knowledge stands out as a congenital character. Let us admit finally that the mind of man is for the most part a congenital product, and the factors which determine it are racial and familial; we are not dealing with a mutable characteristic capable of being moulded by the doctor, the teacher, the parent or the home environment."[1]

Following upon reports to the Governments of Sweden and New Zealand favouring the sterilisation of mental defectives, and a vigorously worded plea by Mr. Harold Cox in the *Spectator* for this method of racial purification in Great Britain, cogent arguments in favour of the proposal were set forth in the *Times* for January 18 over the signatures of ten distinguished members of the medical profession. Claiming a "wide practical knowledge of mental deficiency" denied to these specialists, four office-bearers of the Central Association for Mental Welfare replied that the preventive effect would be slight and the resultant social evil considerable. Of the ensuing correspondence little can be said, except that it showed the conditions to be more favourable to argumentation about the problem than to the formation of sound opinion.

---

[1] "Problem of Alien Immigration," by Karl Pearson and Margaret Moul, *Annals of Eugenics*, vol 1, pt. I. Cambridge: University Press.

One of the duties of local authorities under the Mental Deficiency Act 1913 is "ascertainment." The total number of mental defectives "ascertained" up to the end of 1924 (England and Wales) was 48,778, for whom six local authorities have "realised the urgency of provision [of care] and have acquired estates on which to establish colonies." But ascertainment varies in different districts. In Oxford County Borough it is 4·17 a thousand; in South Shields County Borough it is 0·10 a thousand. Sixty-four local authorities have not yet "ascertained" one in a thousand of their populations, partly from inertia or parsimony or official discouragement, or a knowledge that all available accommodation was full to overflowing. But six local authorities average 3·28 a thousand. If this incidence prevailed for the whole country (and the true average as it affects the fitness of the population is not lower, but far higher), a number comparable with the total of lunatics at present under care would be added to the "ascertained" mental defectives. There appears to be no reason why a segregated mental defective should cost less to keep than a segregated lunatic, and there are at present 19,376 defectives in institutions similar to those provided for lunatics. This much is clear, then, that to pursue an adequate policy of segregation would involve the addition to the nation's incapacity bill of a sum comparable with the present lunacy administration, or about 7,000,000*l.* a year.

Setting aside the unpractical suggestion of the Board of Control that, since "one of the most serious difficulties arises from the fact that patients on licence are naturally apt to form friendships with members of the opposite sex, . . . we advise that whenever a defective who is out on licence appears to be contracting relationships with the opposite sex, the fact should be reported to the Local Authority concerned with a view to their taking such action as they may think is called for . . .,"[2] two proposals remain: (1) Sterilisation, which, in the language of the Board, "one or two Local Authorities and a judge of the High Court have even suggested"; and (2) the restriction of immigration.

The arguments put forward in favour of sterilisation are its simplicity and its efficacy so far as individual propagation is concerned. In the female, it is now customarily performed in the numerous cases where pregnancy is terminated by Cæsarean section owing to the presence of contracted pelvis. As so performed, each Fallopian tube is ligatured twice and the tube divided between the ligatures. In the male, the operation involves no entry into the abdomen and is thus of shorter duration, involving only an incision through the skin along the line of the vas deferens, separation of that tube from the accompanying blood-vessels, and its section, as in the female, between ligatures. On the whole, there is more rather than less to be said in favour of the operation in the female than in the male. There is now an extensive surgical experience of its good results. In the male, obliteration of the vas deferens, where it has occurred accidentally, has led to swelling of the testis, and the after-effects of ligature on both sides at puberty are not well known. But simple modifications of the operation in the male can be devised to obviate retention of the secretion from which alone these results can arise.

Objection to sterilisation is made on several grounds the validity of which in most cases it would be very difficult to prove.

(1) *That it does not obviate the necessity for institutional treatment.* It is clear, from police and other sources, that large numbers of defectives not yet ascertained do need care of one kind or another. The following case is from an area where "ascertainment" was only 0·38 a thousand. A mentally defective girl of 21 years of age. She was found to be suffering from venereal disease and to be pregnant. She is described as an imbecile suffering from partial paralysis to an extent which made it doubtful if she could survive her confinement. A charge was brought against her brother, a boy of seventeen, for having sexual intercourse with his sister. The family consisted of father and mother, said to be rather abnormal and simple, and a brother said to be feeble-minded. The imbecile girl and her feeble-minded brother slept in one bed. The judge said: "It is not for me to decide who is responsible for the terrible state of affairs which exists in your home. . . . Somebody is responsible for it, but I regard you as the victim and not the guilty person."[3] It is doubtful here whether any local authority would have considered segregation necessary for the father and mother; yet sterilisation would have served had it been practised.

Large numbers of cases might receive only relatively brief institutional treatment if sterilised in place of lifelong segregation, which is the *sine qua non* of the segregationists.

---

[2] Eleventh Annual Report of the Board of Control, p. 79. (H.M. Stationery Office.)

[3] Eleventh Annual Report of the Board of Control.

(2) *That many parents of defectives are not themselves defective.* From considerable personal acquaintance with mental defectives and their relatives, we are most suspicious of all evidence which appears to lend any support to this contention, notwithstanding the opinion of Prof. Jennings (of Johns Hopkins University) that "whatever eugenic measures are attempted, so long as biparental inheritance is kept up, the variety, the surprises, the perplexities, the melodrama that now present themselves among the fruits of the human vine will continue." It is a subject in which all manner of circumstances conspire to mislead the inquirer. While congenital malformations involving deficiency arise frequently and apparently sporadically, they give rise in most cases to extreme forms of mental defect and are almost wholly incompatible with social (or anti-social) behaviour. Such cases do not constitute a social problem and must not be confused with the degenerate tendencies which do.

(3) *That sterilisation might lead to a false sense of security and involve the intensification of other evils.* The irony of this argument lies chiefly in its source—those who claim "practical" knowledge of mental deficiency. It supposes an *absence* of the normal powers of self-control, prevision and obedience to social convention, and pretends that licence would result from the removal of the need for what is absent. Or it supposes that advantage would be taken by normal individuals of the sterilisation of imbeciles! The argument is scarcely worthy of serious consideration.

(4) *Popular opposition.* Probably, if the truth were known, the general public would go much further than any Government is likely to ask it to go for years to come.

There remains the alien contribution to racial deterioration. There appears to be no reason why we should not at least adopt the sound advice of Prof. Karl Pearson and his collaborator, founded on a basis of scientific inquiry foreign to official control: "Let us set a standard for immigrants, say 25 per cent higher than the mental and physical averages of the native population—and in the present state of our medical, physical and psychological anthropometry this is not an idle dream—and let us allow none to enter who fails to reach this standard."

There are many points upon which biologists may and do disagree with Prof. Karl Pearson, but it would be difficult to think of any one more pre-eminently fitted to direct such an investigation as would bring order out of the chaos of official facts and fancies and equip the nation with sound principles for action. Of clear knowledge at present we have next to none.

Fruit and Fruit Growing.

(1) *A Handbook of Hardy Fruits more commonly grown in Great Britain: Stone and Bush Fruits, Nuts, etc.* By Edward A. Bunyard. Pp. 258. (London: John Murray, 1925.) 10*s.* 6*d.* net.

(2) *Systematic Pomology.* By U. P. Hedrick. (The Rural Science Series.) Pp. xviii+488+24 plates. (New York: The Macmillan Co., 1925.) 17*s.* net.

(3) *The Lorette System of Pruning.* By Prof. Louis Lorette. Translated by W. R. Dykes. Pp. xliv+166. (London: Martin Hopkinson and Co., Ltd., 1925.) 7*s.* 6*d.* net.

(1) THIS book is the second and concluding volume of a work designed by the author to fill the place formerly occupied by Dr. Hogg's "Fruit Manual." The latter has been generally accepted by pomologists as the standard work of reference on varieties of fruit grown in Great Britain since it first appeared some fifty years ago, but nearly forty years have elapsed since the issue of the last edition. During that interval many of the most popular and widely grown present-day varieties have been raised and introduced and there has been, accordingly, an obvious need for either an up-to-date edition of the "Fruit Manual" or a new work of a similar character. For the preparation of such a work there is probably no British pomologist better qualified to undertake the task than Mr. Edward Bunyard.

The work lays no claim to completeness, the author stating in his preface to the first volume that he considers it unwise to include descriptions of varieties other than those which are more generally cultivated. Some limitation of the sort is necessary in a handbook of relatively modest size, for the number of varieties of the common hardy fruits grown in Great Britain is far larger than generally supposed. The element of selection of material thus introduced inevitably exposes the work to criticism as to the right of place of many of the sorts described. In the volume under review, which treats of all the hardy fruits except the apple and pear, a noteworthy omission is the Warwickshire Drooper plum, a variety of frequent occurrence in the important Evesham plum-growing area, while other sorts rarely met with outside a few nurseries and private gardens are included. Among strawberries, there is no reference to Laxton and Monarch, two kinds of some vogue in the earlier years of the present century, or to Ruskin, a leading Scotch variety.

Notwithstanding omissions of this kind, the book is of real assistance to the systematic pomologist, for the varietal descriptions are generally accurate, concise, and mostly the result of first-hand observation, which has enabled doubtful identities to be cleared up. In the case of cherries and red currants particularly the work gains added value and interest from the author's own investigations in the systematics of those fruits.

(2) Prof. Hedrick's book on systematic pomology serves in many respects a similar purpose for the student of fruit culture in the United States and Canada. The more important and interesting varieties of hardy fruits grown in North America are described briefly; their history, when known, stated; and the author's conclusions on their merits generally given. Included in the list of sorts described are several kinds of European origin, and it is interesting to compare the observations on these growing under North American conditions with those on the same varieties under English conditions recorded in Bunyard's handbook. A similar remark applies to the varieties of American origin included in both works. It is suggestive of the different influence of American and English conditions to find the Ribston Pippin apple, now generally discarded in Great Britain on account of its susceptibility to canker, described by Hedrick as a variety producing hardy, vigorous, and long-lived trees; at the same time, Cox's Orange Pippin, the leading English dessert apple, also like Ribston Pippin a delicate sort, has not been considered of sufficient importance in American pomology to merit inclusion.

As the title indicates, the scope of this work is wider than that of the preceding. Systematic pomology, as defined by the author, is the study of the kinds of fruits and their relationships. He has, accordingly, in a series of introductory chapters, given a brief general description of the structure and arrangements of the various organs to enable the student to grasp the principles upon which the classification of varieties of the respective kinds of fruits is based. The volume is intended primarily for classroom work, and largely comprised of abbreviated material taken from the author's "Cyclopedia of Hardy Fruits" and the elaborate monographs on various fruits which have been prepared by him and published by the State of New York. It fills a distinct gap in pomological literature and, although concerned with American material, should prove of use as well as interest to pomologists generally.

(3) The third volume of the group is a translation of the fourth French edition of Prof. Lorette's book on his methods of pruning fruit trees, by the late Mr. W. R. Dykes, secretary of the Royal Horticultural Society.

The volume is mainly a description of a system of pruning evolved by the author after many years of practical trials at the School of Agriculture at Wagnonville, near Douai. The essence of the system is that the normal practice of pruning in winter is entirely discarded in favour of a series of summer treatments applied chiefly in June and July. By this means it is claimed that the energies of the tree can be concentrated on fruit production, the formation of unnecessary shoot growth being prevented. While at first sight the drastic removal of young leafy shoots in the height of the summer may appear to reduce rather than improve the tree's chance of accumulating adequate organic reserve food materials necessary for blossom and fruit formation, it is asserted that the result is the production of a large leaf area so situated that it promotes the development of fruit buds instead of unwanted extensive shoots. Suitable manuring is at the same time regarded as essential to maintain vitality.

The author lays stress on the individual details of his system, which render it fundamentally distinct from the older, generally practised form of summer pruning. Special attention is given to the form of the tree and the production of an evenly balanced branch system, in which the forced growth of "stipulary" buds plays an important part. The spacing of individual branches is another feature of particular concern. The directions for treatment given, which refer chiefly to the pear, are those which have yielded best results at Wagnonville, but minor modifications are considered necessary according to soil and climate. This point will be appreciated by those who have tried the method in some of the rainier districts in Great Britain.

Some measure of support for the system on scientific grounds is forthcoming from recent research on pomological physiology. In the original French the exact meaning of the author was not clear in places. The translator has allowed himself some latitude with advantage, and does well to direct attention to the difficulties arising from the want of an accepted nomenclature for the various types of lateral shoots of fruit trees.

The merits of the system have already been much debated, but there can be no doubt of the service which the author has rendered to scientific pomology in securing attention to the fundamental principles underlying all methods of pruning.

Biological Problems.

La concentration en ions hydrogène de l'eau de mer—le pH: méthodes de mesure; importance océanographique, géologique, biologique. Par R. Legendre. (Les problèmes biologiques.) Pp. vii + 291. (Paris: Les Presses universitaires de France, 1925.) 30 francs.

UNDER the above general title a series of monographs is being issued by the University Press, Paris. Of these the volume under review is the third. Dr. R. Legendre, Director of the Laboratory of Comparative Physiology in the École des Hautes Études, Paris, is indeed to be congratulated upon the production of his monograph. It is well printed, lucid, contains a vast amount of detail skilfully woven into a consideration of a surprisingly large number of physiological and geological themes, and is, in short, interesting from cover to cover. It is to be hoped that it will have many English readers, for those in search of problems for research are given a wide field from which to select if they read the book.

Somewhat more than one-third of the book is devoted to a description of the methods of measuring hydrogen ion concentration; details necessary for practical work are given as well as a theoretical introduction to the subject—this, moreover, is written especially for the weak brother and is developed from a few fundamental principles. Chapters 2-4 deal with the alkalinity of sea-water, its changes with depth, season, and latitude, its relation to the precipitation of calcium carbonate and to the nature of oceanic deposits. This portion is of especial interest to the hydrographer and the geologist.

The remaining third of the book is occupied by a discussion of the biological problems which are connected with the hydrogen ion concentration or *p*H value of the sea. They include researches on respiration, photosynthesis, the mineral constituents of marine plants and animals, seasonal changes in the plankton, tropisms, composition of intracellular liquids, permeability, isoelectric points, ciliary movements, and the maturation, fertilisation, parthenogenesis, and division of the egg. There is also a brief, but useful, appendix on methods of maintaining sea-water in a condition fit for marine animals and upon artificial sea-water. A notable feature of the book is the large number of references given both to early and to the most recent work, including many researches carried out by Dr. Legendre himself, a fact which ensures that the volume is critical throughout and no mere compilation.

The reviewer would, however, point out that, in common with other distinguished physiologists, the author writes of the "tension" exerted by aqueous vapour and by carbon dioxide, instead of using the correct term pressure. As an example of the confusion due to the use of the term "tension" we may consider the Clark hydrogen electrode vessel, containing hydrogen gas—which exerts a pressure—also water vapour and carbon dioxide exerting "tensions" The total pressure is found by adding the pressure to the two "tensions."

A list of errata is issued with the book. In addition the following have been noted: P. 112, in ll. 1, 3, and 4 B means any monovalent base, but in l. 2 it stands for the element boron; p. 112, l. 17, for "mai" read "mars"; p. 147, l. 9 from bottom, for "mai" read "octobre."

It may also be remarked that C. B. Lipman's recent paper (Publ. No. 340, Carnegie Inst.) has shown that the views formerly put forward, concerning the precipitation of calcium carbonate in tropical waters being due to denitrifying bacteria, are incorrect. Winkler's method of estimating oxygen is given on p. 189 as involving titration with sodium sulphite, but thiosulphate is more generally used. The statement on p. 275 that artificial sea-water "ne permet jamais aucune culture" appears to be rather too vigorous an interpretation of Allen's results, and those of Drummond and Peach have, moreover, to be considered.

In conclusion, it may be said that the book augurs well for the success of the series, and is heartily recommended.

W. R. G. A.

Experimental Physics.

(1) *A Laboratory Manual of Experiments in Physics.* By Prof. Leonard Rose Ingersoll. Pp. ix+220. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 10*s.* net.

(2) *Heat: an Elementary Text-Book.* By Dr. Ivor B. Hart. (Bell's Natural Science Series) Pp. vii+226. (London: G. Bell and Sons, Ltd., 1925.) 3*s.* 6*d.*

(3) *Practical Physics: for the Use of Students of Natural Philosophy.* Part 2. (By the Staff of the Department.) Pp. 71. (Melbourne: Melbourne University Press, 1925.) n.p.

(4) *Individual Work in Science.* By Herbert McKay. Part 1. Pp. vii+97. Part 2. Pp. vii+97. Part 3. Pp. vii+97. 1*s.* 3*d.* each. Part 4: Teacher's Book. Pp. vii+95. 3*s.* 6*d.* (London: University of London Press, Ltd., 1925.)

(5) *An Introduction to Physical Science.* By Dr. Ivor B. Hart. Pp. xii+306. (Oxford: Clarendon Press; London: Oxford University Press, 1925.) 4*s.* net.

These books under notice are mostly concerned with instruction in practical physics, although their standard varies from that of an honours university course to an introductory school course.

(1) Prof. Ingersoll's laboratory manual of experiments in physics embodies the work of the elementary class in the University of Wisconsin. The book is prefaced by a useful introduction dealing with curve plotting, averages, errors, etc., and then proceeds to simple exercises with measuring instruments. There is little that requires comment in the selection of experiments, seventy-six in all, except that the section devoted to light, which contains only nine experiments, seems rather inadequate.

(2) The author of "A Student's Heat" has here

reproduced the elementary parts of that text-book with the view of meeting the requirements of matriculation students. The book follows orthodox lines and is well furnished with examples of a practical character. The historical aspect of the subject is not overlooked, and although the book is not intended to assist the student in carrying out laboratory exercises, the necessary fundamental experiments are well described and illustrated.

(3) The third book on our list is a series of about fifty experiments forming part of the physics course at the University of Melbourne. It ranges from the synthesis of periodic curves to the measurement of alpha-rays. The experiments are mostly of standard type, although some involve the use of apparatus (Prestwich fluid gauge, slip gauges, Michell viscometer) not commonly found in physical laboratories. It is a useful compilation.

In (4) we pass to the other end of the scale, the three small books included in this set being designed to meet the need of school teachers for small inexpensive books from which beginners can work with a minimum of supervision. Each book covers a one-year course in elementary physics, with forty-eight lessons distributed over the various branches of the subject. The course is well planned and carefully thought out, the experiments are concisely but sufficiently described, and most of the apparatus required is either home-made or easily procured.

An additional volume for the guidance of the teacher contains lists of the apparatus required, and gives suggestions for the distribution of the experiments in the class. The standard reached, even in the third-year course, is very elementary, and with the exception of the sections on measurement and mechanics, is almost wholly qualitative, but it provides a good introduction to the subject.

(5) The volume which appears at the end of our list is an introduction to physical science intended to steer a middle course between the Scylla of excessive concentration on accurate measurement and the Charybdis of snappy description of everyday physics divorced from the discipline of practical work. The author has certainly succeeded in producing a very attractive volume. The subjects are treated in an interesting and practical way, the illustrations are numerous and good, while the paper and type add considerably to the pleasure of using the book. The main defect is a lack of proportion in the treatment of the various branches of the subject. Magnetism, static electricity, and current electricity are dismissed in 28 pages, containing only two practical exercises, both in magnetism. On the other hand, the excellent section on hydrostatics extends to 82 pages and contains more than twenty practical exercises.

Our Bookshelf.

Port Development. By Dr. Roy S. MacElwee. Pp. xv+456. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 25*s*. net.

THE subject of port development may be regarded from two points of view: (1) physical, or constructional, and (2) commercial. It is from the latter viewpoint that Dr. MacElwee has written the work under notice, and in it he considers the various factors which make for the prosperity of a port, serve to foster its trade and to extend its influence. The Americans have a phrase which expresses their idea of treating the port itself as a negotiable instrument: they speak of "selling a port," meaning the disposal of its facilities to commercial and shipping customers. As Dr. MacElwee truly remarks, "Terminal facilities alone, important as they are, will not make a port a successful commercial gateway." It is necessary to impress the trading community with the advantages to be gained by making use of them, and, in this connexion, propaganda work, and "solicitation" (Anglicé, canvassing) are of the greatest importance.

Dr. MacElwee is already well known in port circles on both sides of the Atlantic as the author of several works including "Ports and Terminal Facilities," the success of which has led him to amplify his treatment of the subject. In the present volume he deals with that section which comprises government administration, traffic and solicitation. The field admits of a wide purview and the book consists of four parts. Part I. treats of port development as a matter for serious consideration, and its value, nationally and locally. Part II. institutes a comparison between various typical ports of the world, with an analysis of their attractions to shipping. Part III. deals more particularly with details of port competition: balanced cargoes, tonnage markets, rail and water rates, etc., together with the costs and services at the respective terminals. Part IV. is devoted to the subject of free ports, that is, port areas which are exempt from the imposition of duties on goods landed for re-export.

As Commissioner of a thriving American port, with a wide personal experience extending to ports in the old world as well as the new, Dr. MacElwee writes with a thorough knowledge of his subject. He has collected a large amount of information from a number of sources, and his book will therefore prove a valuable work of reference.

B. C.

The Scent of Flowers and Leaves: its Purpose and Relation to Man. By F. A. Hampton. Pp. vii+135. (London: Dulau and Co., Ltd., 1925.) 6*s*. net.

THIS book is in no sense a compilation, but a valuable contribution to the small literature of odour. The author offers a sound, but non-technical, review of theories of odour, and his classification of flower scents appears to be the best yet made. It is a revision of the suggestions of Kerner von Marilaun, bringing them up-to-date. For this, the author's qualifications are unique, as he successfully combines data from many fields in which he has experience. Previous classifications of odours have been incompletely documented by sponsors experienced in one or two branches of science, and, while much remains to be done to systematise our knowledge of smell, the present classification is very suggestive. Much space is devoted to a discussion of the origin and development of scent, its function in the plant and elsewhere, and to our appreciation of it. The author's theory of human reaction to scents will be more acceptable than the crude and somewhat malodorous treatment usually accorded by the psychologist to the subject.

Garden lovers in the study, especially those planning a garden, will be greatly indebted to Dr. Hampton for the wealth of information on the history of scented plants and the arrangement of a scented garden *Rosa gallica* (the Rose of Provins) is mentioned, but no connected history of this early variety is given. Printers' errors appear to be absent. The repeated spelling "benzine" and the use of "benzoloid" are unfortunate; "stereoptene" should be "stearoptene," and a much fuller index would be valuable. The statement that citral is the scent substance of citronella requires qualification.

The book has a pleasant literary style, and possesses personality. On account of the many interests associated with floral perfume, "Flower Scent" is certain to make a wide appeal, and needs only to be read to be enjoyed.

HUGH NICOL.

Macrophotographie et microphotographie. Par F. Monpillard. (Encyclopédie scientifique: Bibliothèque de photographie.) Pp. xxxi+671. (Paris: Gaston Doin et Cie, 1925.) 25 francs.

THE two branches of the subject are not sharply distinguished, but, speaking generally, macrophotography concerns objects that are large enough to be seen, with at least some detail, by the naked eye, and need only a low magnification, if any, so that they are conveniently photographed by a lens of short focal length attached directly to the camera. Examples given by the author are a group of mounted butterflies and physiological dissections and preparations. Microphotography is the photography of smaller objects with higher magnifications, such that the use of a microscope stand is very desirable if not necessary. Many details are common to both methods of work, so that there is a distinct advantage in treating them together, especially as macrophotography is too often neglected in present-day text-books as belonging neither to ordinary photography nor (as we prefer to call it) photomicrography.

The author includes the use of polarised light, microspectrography, metallography, instantaneous microphotography and microcinematography, photography by means of ultra-violet light, stereoscopic work, microradiography, and stereoradiography. So many subjects obviously cannot be treated at great length in the space available, but the salient points of modern methods are given, and also a good deal of historical matter. It would be advantageous if the illustrations were of better quality and rather more numerous, and we may add that Mr. W. Thorp's method of making grating replicas was not by pressing with an hydraulic press thin celluloid upon an original Rowland grating, as is stated, but by pouring a solution of celluloid upon the original, and then stripping and mounting the resulting film. The volume should certainly be welcomed by scientific workers.

The Daubeny Laboratory Register, 1916–1923: with Notes on Scientific Researches carried out by Members of Magdalen College, Oxford. By R. T. Gunther. Vol. 3. Pp. vii+297-532. (Oxford: The Laboratory, Magdalen College, 1924.) 10*s.* 6*d.*

TWENTY years ago, Mr. Gunther published the first volume on the origin and history of Daubeny's principal benefactions to Magdalen College, Oxford, and in 1915 this was followed by a second volume. He now adds a third volume on work in the Daubeny laboratory from 1916 to 1923, and expresses regret that it is no longer possible to use Daubeny's building for scientific research or the housing of his collection. Changed conditions in the University seem to have been regarded as justifying the closing of the laboratory in 1923.

Mr. Gunther refers to his own researches in the volcanic region of Naples, which were directly stimulated by Daubeny's work and the collections he left to the College. He also gives some account of the recent discovery of Pleistocene mammalian remains in the College grounds, and publishes photographs of some fossil crocodilian vertebræ from the Kimmeridge Clay of Shotover, which appear to be unique in showing stains of the adjacent blood-vessels.

In addition to the record, the volume includes notes on some of the early naturalists associated with Magdalen College, and on others who have undertaken scientific research there. It also incorporates much matter of historical interest to the College, which Mr. Gunther has recovered from the archives while pursuing his researches on early science at Oxford.

The Dynamo: its Theory, Design, and Manufacture. By C. C. Hawkins. Sixth edition, revised throughout and largely rewritten. Vol. 3: *Alternators.* Pp. xviii+572. (London: Sir Isaac Pitman and Sons, Ltd., 1925.) 30*s.* net.

IN this volume the author discusses the design and working of the generators which produce alternating current. So many books and papers have recently been published on the subject that he finds it necessary only to give a rapid résumé of some modern developments. He confines himself to the more practical side of his subject, and the dynamo designer can at once compare his own formulæ with those given by the author. In 1909 Sir Thomas Lyle gave his theory of the alternating current generator to the Physical Society of London. Judging by results, however, it has proved a little too difficult for the practical designer and it is not mentioned by the author. To the student, however, it would prove interesting and instructive. The chapters on the turbo-alternator and the parallel running of alternators have been carefully written and should prove helpful to the engineer. The author, when discussing armature reaction, adopts and strongly advocates the two-reaction method of A. Blondel. This phenomenon is barely mentioned in the older books. For a full discussion of it a theory similar to Lyle's would have to be devised. We can recommend this volume to dynamo designers.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Spinning Electrons and the Structure of Spectra.

So far as we know, the idea of a quantised spinning of the electron was put forward for the first time by A. K. Compton (*Journ. Frankl. Inst*, Aug. 1921, p. 145), who pointed out the possible bearing of this idea on the origin of the natural unit of magnetism. Without being aware of Compton's suggestion, we have directed attention in a recent note (*Naturwissenschaften*, Nov. 20, 1925) to the possibility of applying the spinning electron to interpret a number of features of the quantum theory of the Zeeman effect, which were brought to light by the work especially of van Lohuizen, Sommerfeld, Landé and Pauli, and also of the analysis of complex spectra in general. In this letter we shall try to show how our hypothesis enables us to overcome certain fundamental difficulties which have hitherto hindered the interpretation of the results arrived at by those authors.

To start with, we shall consider the effect of the spin on the manifold of stationary states which corresponds to motion of an electron round a nucleus. On account of its magnetic moment, the electron will be acted on by a couple just as if it were placed at rest in a magnetic field of magnitude equal to the vector product of the nuclear electric field and the velocity of the electron relative to the nucleus divided by the velocity of light. This couple will cause a slow precession of the spin axis, the conservation of the angular momentum of the atom being ensured by a compensating precession of the orbital plane of the electron. This complexity of the motion requires that, corresponding to each stationary state of an imaginary atom, in which the electron has no spin, there shall in general exist a set of states which differ in the orientation of the spin axis relative to the orbital plane, the other characteristics of the motion remaining unchanged. If the spin corresponds to a one-quantum rotation there will be in general two such states. Further, the energy difference of these states will, as a simple calculation shows, be proportional to the fourth power of the nuclear charge. It will also depend on the quantum numbers which define the state of motion of the non-spinning electron in a way very similar to the energy differences connected with the rotation of the orbit in its own plane arising from the relativity variation of the electronic mass. We are indebted to Dr. Heisenberg for a letter containing some calculations on the quantitative side of the problem.

This result suggests an essential modification of the explanation hitherto given of the fine structure of the hydrogen-like spectra. As an illustration we may consider the energy levels corresponding to electronic orbits for which the principal quantum number is equal to three. The scheme on the left side of the accompanying figure (Fig. 1) corresponds to the results to be expected from Sommerfeld's theory. The so-called azimuthal quantum number k is defined by the quantity of moment of momentum of the electron about the nucleus, $kh/2\pi$, where $k = 1, 2, 3$. According to the new theory, depicted in the scheme[1] on the right, this moment of momentum is given by $Kh/2\pi$, where $K = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}$. The total angular momentum of the atom is $Jh/2\pi$, where $J = 1, 2, 3$. The symbols K and J correspond to those used by Landé in his classification of the Zeeman effects of the optical multiplets. The letters S, P, D also relate to the analogy with the structure of optical spectra which we consider below. The dotted lines represent the position of the energy levels to be expected in the absence of the spin of the electron. As the arrows indicate, this spin now splits each level into two, with the exception of the level $K = \frac{1}{2}$, which is only displaced.

In order to account for the experimental facts, the resulting levels must fall in just the same places as the levels given by the older theory. Nevertheless, the two schemes differ fundamentally. In particular, the new theory explains at once the occurrence of certain components in the fine structure of the hydrogen spectrum and of the helium spark spectrum which according to the old scheme would correspond to transitions where K remains unchanged. Unless these transitions could be ascribed to the action of electric forces in the discharge which would perturb the electronic motion, their occurrence would be in disagreement with the correspondence principle, which only allows transitions in which the azimuthal quantum number changes by one unit. In the new scheme we see that, in the transitions in question, K will actually change by one unit and only J will remain unchanged. Their occurrence is, therefore, quite in conformity with the correspondence principle.

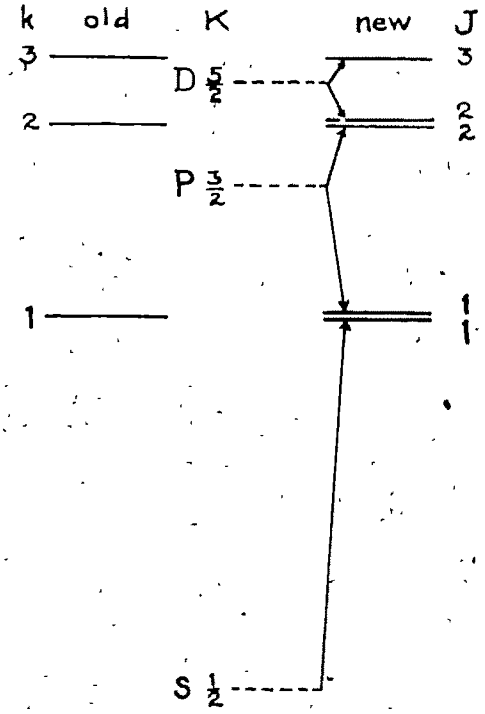

FIG. 1.

The modification proposed is specially important for explaining the structure of X-ray spectra. These spectra differ from the hydrogen-like spectra by the appearance of the so-called "screening" doublets, which are ascribed to the interaction of the electrons within the atom, effective mainly through reducing the effect of the nuclear attraction. In our view, these screening doublets correspond to pairs of levels which have the same angular momentum J but different azimuthal quantum numbers K. Consequently, the orbits will penetrate to different distances from the nucleus, so that the screening of the nuclear charge by the other electrons in the atom will have different effects. This screening effect will, however, be the same for a pair of levels which have the same K but different J's and correspond to the same orbital shape. Such pairs of levels were, on the older theory, labelled with values of k differing by one unit, and it was quite impossible to understand why these so-called "relativity" doublets should appear separately from the screening doublets. On our view, the doublets in question may more properly be termed "spin" doublets, since the sole reason for their appearance is the difference in orientation of the spin axis relative to the orbital plane. It should be emphasised that our interpretation is in complete accordance with the correspondence principle as regards the rules of combination of X-ray levels.

---

[1] Quite independently of the ideas discussed here, a scheme of levels corresponding to this figure has been previously proposed by the writers (*Physica*, 5, 266, 1925), on the ground of the formal analogy between spectral structures. From similar formal considerations, this scheme has recently also been arrived at by J. C. Slater (*Proc. Washington Acad.*, December 1925).

The assumption of the spinning electron leads to a new insight into the remarkable analogy between the multiplet structure of the optical spectra and the structure of X-ray spectra, which was emphasised especially by Landé and Millikan. While the attempt to refer this analogy to a relativity effect common to all the structures was most unsatisfactory, it obtains an immediate explanation on the hypothesis of the spin electron. If, for example, we consider the spectra of the alkaline type, we are led to recognise in the well-known doublets regular spin doublets of the character described above. In fact, this enables us to explain the dependence of the doublet width on the effective nuclear charge and the quantum numbers describing the orbit, as well as the rules of combination.

The simplicity of the alkaline spectra is due to the fact that the atom consists of an electron revolving round an atomic residue which contains only completed electronic groups, which are magnetically inert. When we pass to atoms in which several electrons revolve round a residue of this kind we meet with new features, since we have to take account of other directing influences on the spin axis of each electron besides the couple due to its own motion in the electric field. Not only does this enable us to account for the appearance of multiplets of higher complexity, but it also seems to throw light on the so-called "branching" of spectra, which usually accompanies the adding of a further electron to the atom, and for which hitherto no satisfactory explanation has been given. In fact, it seems that the introduction of the concept of the spinning electron makes it possible throughout to maintain the principle of the successive building-up of atoms utilised by Bohr in his general discussion of the relations between spectra and the natural system of the elements. Above all, it may be possible to account for the important results arrived at by Pauli, without having to assume an unmechanical "duality" in the binding of the electrons.

So far we have not mentioned the Zeeman effect, although the introduction of the spinning electron was primarily suggested by the analysis of the anomalous Zeeman effects shown by the components of multiplet structures. From the point of view of the correspondence principle, this effect shows that the influence of a magnetic field on the motion of the atom differs considerably from that to be expected if the electron had no spin. In fact, from the well-known theorem of Larmor we would expect the effect on any spectral line to be of the simple Lorentz type, quite independently of the character of the multiplet structure. Therefore the appearance of the anomalous Zeeman effects has hitherto presented very grave difficulties. However, these difficulties disappear at once when, as assumed, the electron has a spin and the ratio between magnetic moment and angular momentum of this spin is different from that corresponding to the revolution of the electron in an orbit large compared with its own size. On this assumption the spin axis of an electron not affected by other forces would precess with a frequency different from the Larmor rotation. It is easily shown that the resultant motion of the atom for magnetic fields of small intensity will be of just the type revealed by Landé's analysis. If the field is so strong that its influence on the precession of the spin axis is comparable with that due to the orbital motion in the atom, this motion will be changed in a way which directly explains the gradual transformation of the multiplet structure for increasing fields known as the Paschen-Back effect.

It seems possible on these lines to develop a quantitative theory of the Zeeman effect, if it is assumed that the ratio between magnetic moment and angular momentum due to the spin is twice the ratio corresponding to an orbital revolution. At present, however, it seems difficult to reconcile this assumption with a quantitative analysis of our explanation of the fine structure of levels. In fact it leads, in a preliminary calculation, to widths of the spin doublets just twice as large as those required by observation. It must be remembered, however, that we are here dealing with problems which for their final solution require a closer study of quantum mechanics and perhaps also of questions concerning the structure of the electron.

In conclusion, we wish to acknowledge our indebtedness to Prof. Niels Bohr for an enlightening discussion, and for criticisms which helped us distinguish between the essential points and the more technical details of the new interpretation.

G. E. UHLENBECK.
S. GOUDSMIT.
Instituut voor Theoretische Natuurkunde,
Leyden, December 1925.

HAVING had the opportunity of reading this interesting letter by Mr. Goudsmit and Mr. Uhlenbeck, I am glad to add a few words which may be regarded as an addition to my article on atomic theory and mechanics, which was published as a supplement to NATURE of December 5, 1925. As stated there, the attempts which have been made to account for the properties of the elements by applying the quantum theory to the nuclear atom have met with serious difficulties in the finer structure of spectra and the related problems. In my article expression was given to the view that these difficulties were inherently connected with the limited possibility of representing the stationary states of the atom by a mechanical model. The situation seems, however, to be somewhat altered by the introduction of the hypothesis of the spinning electron which, in spite of the incompleteness of the conclusions that can be derived from models, promises to be a very welcome supplement to our ideas of atomic structure. In fact, as Mr. Goudsmit and Mr. Uhlenbeck have described in their letter, this hypothesis throws new light on many of the difficulties which have puzzled the workers in this field during the last few years. Indeed, it opens up a very hopeful prospect of our being able to account more extensively for the properties of elements by means of mechanical models, at least in the qualitative way characteristic of applications of the correspondence principle. This possibility must be the more welcomed at the present time, when the prospect is held out of a quantitative treatment of atomic problems by the new quantum mechanics initiated by the work of Heisenberg, which aims at a precise formulation of the correspondence between classical mechanics and the quantum theory.

N. BOHR.
Copenhagen, January 1926.

Carnot's Cycle and Efficiency of Heat Engines.

In NATURE of August 29, 1925, there was published on p. 326 an extract of a paper read by Dr. Haldane before the Institution of Mining Engineers at Cardiff on June 16, in which he advances a somewhat unusual view as regards the efficiency of the Carnot cycle.

A defence of the orthodox view was made by Prof. Porter on October 3, p. 497, and by Mr. Butler on October 24, p. 608. Prof. Porter demonstrates quite clearly that for any given temperatures a higher efficiency is always obtained with the Carnot cycle than with that proposed by Dr. Haldane.

In reply to his critics Dr. Haldane has since published a further paper in which he maintains his original view. Since, however, a correct appreciation of the thermo-dynamics of the cycle of a heat engine underlies all engineering practice, a matter so fundamental should not permit of any misunderstanding. It is, therefore, desirable to determine at what point Dr. Haldane diverges from the orthodox treatment.

The efficiency of a heat engine is the ratio of the heat converted into work to that which is received by the engine from the source of the heat. The Carnot cycle consists of the following processes:

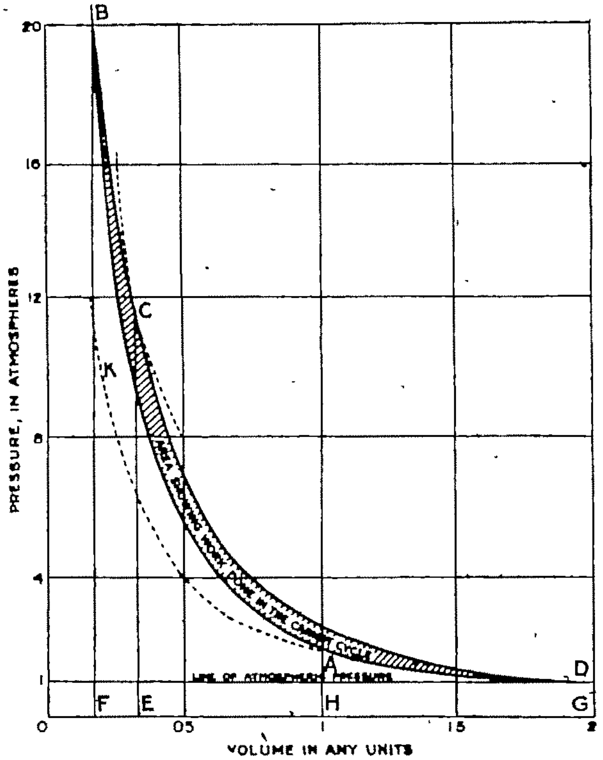

FIG. 1.—Dr. Haldane's diagram of Carnot cycle with lower absolute temperature 50 per cent. below upper.

Isothermal expansion with work done by the working fluid on the piston during the reception of heat.

Adiabatic expansion with work done by the working fluid on the piston at the expense of the intrinsic energy of the fluid.

Isothermal compression during which work is done by the piston on the working fluid whilst heat is rejected; and adiabatic compression during which energy is restored to the fluid equal to the work done on it by the piston.

It is only during one of these processes, namely, isothermal expansion, that the working fluid receives heat from the outside source.

Now Dr. Haldane in his second paper considers the case of a Carnot cycle for a perfect gas with the absolute temperature of the source double the absolute temperature at which heat is rejected, and the efficiency therefore, by the usual theory, 50 per cent. He reasons as follows:

"The work W done by the air during expansion is represented by the area BCDGF [see Fig. 1 reproduced from Dr. Haldane's second paper]. The work w done on the air during compression is represented by the somewhat smaller area BADGF. The net work $W - w$ done in the cycle is represented by ABCD, hence the efficiency is according to the contention of my paper $(W - w)/W$, and we can see at once that this is very small and far below 50 per cent."

It is clear, therefore, that Dr. Haldane is led to a wrong determination of the efficiency of the cycle, because he adopts an unusual valuation for the amount of heat received, which he takes to be equal in equivalent units to the total work done during expansion, whereas the heat actually received by the working fluid from the source of heat is only that which is absorbed during isothermal expansion, and in the case of a perfect gas is equal to the work done during that process only. It is not surprising, therefore, that he arrives at too low a value for the efficiency of the Carnot cycle.

From a careful perusal of Dr. Haldane's papers, he appears to contend that the heat received by the working fluid during the process of isothermal expansion is not the total amount received. There must, he argues, be added the heat equivalent of the work done against the fluid during adiabatic compression in order to arrive at the total heat which the fluid receives.

Since, however, this work of compression is deducted from the work done during expansion in order to arrive at the net work of the engine, it will be seen that it is obtained from the engine itself, and should not be charged against what the engine receives from the source of heat. By so charging it, Dr. Haldane really debits the cycle with this part of the negative work twice over; he uses it to reduce the net work done as in the orthodox treatment, and he also uses it to increase his value for the total heat received.

STANLEY S. COOK.
The Parsons Marine Steam Turbine Co., Ltd.,
Turbinia Works, Wallsend-on-Tyne,
January 25.

REFERRING to Dr. Haldane's recent paper on "The Maximum Efficiency of Heat Engines," an abstract of which appeared in NATURE of August 29, 1925, it was difficult when reading the paper to grasp the precise basis upon which the majority of Dr. Haldane's reasoning rests. Some light was thrown on this obscurity, however, by Dr. Haldane's reply to the discussion of his paper. On p. 409, vol. 69, Part 5, of the *Transactions of the Institution of Mining Engineers*, he says:

"When, however, the amount of heat (supplied) is the same in the two cases, the Carnot cycle is always relatively inefficient as compared with the corresponding Haldane cycle. . . . Prof. Porter quite rightly points out that in the Haldane cycle, the difference between T_1 and T_2 is greater than in the Carnot cycle."

It thus appears that Dr. Haldane maintains that the efficiency of different heat engine cycles must be compared on a basis of a given amount of heat supplied, and not, as in the orthodox view, on a basis of temperature range.

That a temperature range is essential to the working of a heat engine is a matter of common observation, with which, presumably, even Dr. Haldane agrees Carnot summed up the situation in the converse statement "Wherever there exists a difference of temperature, motive power can be produced." Carnot went on to show that the efficiency of a thermo-dynamically reversible cycle is proportional to the temperature range solely, and that for a given temperature range no heat engine cycle can possibly be more efficient than a thermo-dynamically reversible one.

Now Dr. Haldane's cycle is not thermo-dynamically reversible Carnot's cycle is thermo-dynamically reversible; therefore, Dr Haldane's cycle cannot possibly be more efficient than Carnot's cycle. Further, since, by definition, efficiency $= \frac{\text{work done}}{\text{heat supplied}}$, it is evident that efficiency is a ratio independent of the actual magnitudes of the quantities involved, so that to base a comparison of efficiencies on a given quantity of heat is valueless

In his second published reply to his critics, Dr. Haldane abandons this point of view and attacks the particular theorem, that is, he tries to prove that Carnot wrongly assessed the efficiency of a reversible cycle as $1 - (T_2/T_1)$.

The real thermal efficiency, as Dr. Haldane correctly says, is given by the fraction $(H-h)/H$, when H is the total heat communicated to the working substance and h the heat energy or heat equivalent of the work lost in recompression, but, by total heat communicated, Dr. Haldane says he means the heat supplied from the source during isothermal expansion, *plus* the heat accumulated in the working substance during adiabatic compression. This reasoning leads for the efficiency of the Carnot cycle to

$$\left\{\frac{T_1 - T_2}{T_1 + \dfrac{(K_v T_1 - T_2)}{R \log_e x}}\right\}.$$

Since, however (as Dr. Haldane himself admits on p. 394 of his original paper), the work done by the engine during adiabatic expansion is exactly equal to the negative work done during adiabatic compression, it is evident that the only source from which the engine receives its heat is the external source. This is the accepted view, and it leads to Carnot's expression for the efficiency, namely, $1 - (T_2/T_1)$

Chemical Effects produced by Resonance Radiation.

DR. RIDEAL having started an investigation of reactions which we discovered last spring, and which one of us (H. S T) stated publicly in Oxford so late as last October were being further studied, it seems desirable to place on record some of the results to which such further studies have led, especially as they show a marked divergence from the results of Hirst and Rideal (NATURE, 116, 899, December 19, 1925)

We are quite unable to subscribe to the conclusion of Hirst and Rideal that hydrogen and oxygen combine very slowly both in the absence and presence of mercury vapour, and only combine rapidly in the presence of a layer of liquid mercury. Our experiments show that hydrogen and oxygen, with the concentration of mercury vapour obtained by bubbling these gases through liquid mercury at room temperatures, will combine rapidly in the presence of the resonance radiation from the cooled mercury arc Furthermore, we have shown that hydrogen peroxide is a prior product of reaction appearing in marked quantities at high rates of gas flow, whereas with slower rates of flow the peroxide formed decreases and the water formed increases. In this manner we have been able to cause the gases to react to produce either exclusively hydrogen peroxide or mixtures of this with water. We have further shown that many hundred molecules of hydrogen peroxide are produced for every mercury atom passing through the zone of radiation, and that mercuric oxide is formed The removal of mercury vapour in this manner may have given rise to the anomalous results of Hirst and Rideal. In the absence of mercury vapour, no peroxide or water is formed under our experimental conditions, but the shorter wave-lengths in the mercury arc do produce a certain amount of ozonisation, which also occurs even when mercury vapour is present.

The quantity of hydrogen peroxide produced varies with several factors; the rate and composition of gas flow, the temperature, the concentration of mercury vapour, and the intensity of illumination. We shall record in more detail elsewhere the experimental data thus obtained.

Since hydrogen peroxide is demonstrably present in the gas phase, it is obvious that a liquid mercury surface must influence the velocity in some manner, since it has long been known that hydrogen peroxide is readily decomposed at a mercury surface We have, however, no data, in a very considerable body of experimental work, which would assign any of the *photosensitised* process to the liquid mercury Nor does there appear to be any sound theoretical reason why mercury atoms in a liquid surface should be more effective than those in the gas phase. Cario and Franck showed also that the quenching of the fluorescence of mercury vapour by hydrogen was proportional to the chemical reaction which could thereby be produced Secondary effects similar to that just mentioned in the presence of hydrogen peroxide will also effect the velocity in the combination of hydrogen and ethylene and in the combination of hydrogen and carbon monoxide, in these cases, however, adversely. For we have shown that the resonance radiation causes a polymerisation of ethylene with the formation of liquid condensation products, and formaldehyde polymerises to solid products as we pointed out in our initial communication on the subject.

We are inclined to assign the variability of reaction rate in the presence of liquid mercury at room temperature entirely to variations in the concentration of mercury vapour caused by removal as mercuric oxide and irregular renewal due to skin effects on the liquid surface. By operation at higher temperatures (60°-70° C.) such variable behaviour completely disappears, as shown by one of us (A. L. M.) in a recent paper (*J Phys. Chem.*, 30, 34, 1926). Our view is strengthened by actual measurements of absorption of resonance radiation by mercury in the presence of various gases, material which will also shortly be published.

We have markedly improved the technique of the study of the chemical effects produced by resonance radiation as exemplified by the apparatus already described by one of us (A. L M.), and by a new form of apparatus, through which, by building the arc system around the quartz reaction vessel, we avoid the use of quartz-mercury arcs and can operate with Pyrex glass arcs.

Genes and Linkage Groups in Genetics.

IT is clearly profitless to continue this correspondence further, since Prof. MacBride will not keep to the point which I raised The correspondence started because I objected to Prof MacBride attacking the *genetical* theory of linkage owing to his disagreement with the *cytological* interpretations of the chromosome theory. To my mind, he has not only not cleared up this point, but has made confusion worse-confounded by dragging in yet a third issue, namely, the *evolutionary* question of the importance of mutations for phylogeny. I would like, however, to make the following brief remarks

(1) Prof. MacBride has not attempted to answer any of the questions I asked him in my last letter concerning linkage, but has again taken the opportunity of doing something much easier, namely, setting forth his general views about wholly unrelated topics, such as evolution. The only genetical points on which I have gathered his views are (1) that a unit-factor is a " change," which is either a slip or a grave error; (2) that a linkage-group is some sort of constitutional disease. This was, as I wrote in my last letter, the only interpretation which I could put on his statements He has not contradicted this interpretation, so that we must assume he accepts it, although I confess it seems to me to be, quite literally, meaningless. He has further stated that he "does not regard Morgan's units as having any validity whatever." This sweeping statement, of course, also denies all validity to Mendel's units and all factors assumed by subsequent Mendelian workers!

He has not even deigned to give us an explanation (which, on his views, is badly needed) of the old-established fact that whereas in some crosses involving two or more Mendelian factors, the F_2 ratios are different according to which way the factors enter the cross (*i.e.* what is usually called linkage), in other crosses they are not (*i e.* what is usually called independent assortment)

In both my previous letters I have pointed out that I was only concerned with the interpretation of certain well-known genetic facts. Prof. MacBride at one moment refers to the facts I adduced as " elementary Mendelism " and in the next breath denies that they are facts. Until he has discussed them, readers of NATURE may be pardoned if they do not accept his general condemnations.

(2) The statement that Morgan's unit-factors " are avowedly assumed in order to make his observations fit a preconceived theory " is inaccurate, as any one will perceive who looks at the article on Drosophila in " Bibliographica Genetica," vol. 2, or still better Bridges and Morgan, Carnegie Institution Publication, No 327, the section on methods

(3) As Prof MacBride has made some assertions about the unimportance of mutations in evolution, I would refer readers of NATURE to a recent summary of observations on mutations and Mendelising characters in wild species of birds by Stresemann, the well-known ornithologist, in *Verh. Deutsch. Zool Ges*, vol. 30, 1925, which shows how far this view is from the truth.

(4) I cannot leave Mr. Tate Regan's letter of January 16 without a word of comment He mentions various probably mutant characters of fish which, if I understand him aright, tend to appear together in Nature, and this set of characters he calls a " linkage-group." Mr. Regan might have made sure of the definition of a linkage-group before writing his letter I can here only assure him that if he will look the matter up he will find that his usage bears no resemblance whatever to the accepted use and definition. The characters in this case appear together owing to some common developmental cause, which quite possibly may have a single-factor genetic basis. The linkage in a linkage-group is not concerned with individual (zygotic) development, but with the distribution of genetic factors to the gametes; and it is between a number of separate unit-factors which may have no special developmental relationship. To use the term linkage-group as Mr Regan has done would be to confuse the mechanism of developmental physiology with the mechanism of segregation and distribution of the hereditary constitution.

Nitrogen in the Sun.

THE occurrence of nitrogen in the sun is still an open question. No familiar lines, for example, λ3995, have yet been detected in the Fraunhofer spectrum, but the presence of the element is indicated by the cyanogen bands.

It appears that the difficulty of identifying nitrogen by its line spectrum can be traced to the nature of the spectrum itself. Under the ordinary conditions of excitation, nitrogen gives several classes of band spectra, while lines obtained under a higher stimulus, including λ3995, have been assigned by Fowler to N^+. The arc lines of nitrogen itself are evidently lost between these two stages. Kiess (*Journ. Opt. Soc. Am.*, June 1925) has recently elucidated this point. He finds that the chief lines of nitrogen lie either in the extreme ultra-violet or in the extreme infra-red, so that workers confining themselves to the usual spectroscopic region miss them completely.

Kiess has given, in the paper mentioned above, a provisional classification of the arc lines. The principal lines are in the Schumann region, λ1742·81, 1745·31, etc., . . ., but the next strongest group from λ8656 to λ8629 constitutes a *pp′* combination There is another *pp′* group at λ8200, but they come from a higher level. It is interesting to see whether these lines occur in the Fraunhofer spectrum On examining the excellent photographs of the infra-red spectrum of the sun given by Meggers (*Astro. Journ*, vol. 47, p. 1), the presence of some of the lines was clearly observed, while the others were found to occur rather faintly. A complete comparison was not possible, as the author had no access to a full list of the wave-lengths of the infra-red solar lines. Miss C. Payne in her recent monograph " On Stellar Atmospheres " does not mention the occurrence of any nitrogen line in the sun or in any low temperature star The only nitrogen line which can be identified without ambiguity in the stellar sequence is λ3995 This, however, does not occur in the sun; it occurs, according to Payne, first in the *A*o class, and Fowler assigns it to N^+.

If this identification of the arc lines of nitrogen in the sun is verified, it will enable us to fix with some definiteness the energy of dissociation of N_2. Some years ago, the present writer calculated from the experimental data of Langmuir that the energy of dissociation of N_2 is of the order of magnitude $1·50 \times 10^5$ gm calories. Recently, Eucken (*Annalen der Chemie*, Band 440, p. 111) has discussed the thermo-chemical data on this point, and he comes to the conclusion that the energy of dissociation of N_2 cannot be less than $4·4 \times 10^5$ gm. calories, or thrice the value calculated by the present writer. If this were the case, nitrogen would not be dissociated at all in the sun, and the atomic spectrum cannot occur there Calculation shows that it would be appreciably dissociated only in the *A*o class But, as we have already mentioned, these stars show the lines of N^+, coming from a level (*2s*) higher than the normal. Hence Eucken's calculations seem to be quite beyond the mark.

Eucken finds from the same line of argument that the energy of dissociation of O_2 cannot be less than $4{\cdot}25 \times 10^5$ calories.

If this were true, no atomic oxygen can occur in the sun. But it is well known that Runge has identified the oxygen triplet λλ7772, 7774, 7775 in the Fraunhofer spectrum. According to Hopfield, the excitation potential for these lines is from 8 to 9 volts, so that in the sun, oxygen is not only completely dissociated, but also a considerable fraction of O-atoms is brought to a higher level The argument is, therefore, fairly decisive that in the case of O_2, Eucken's calculations are very wide of the mark

Winged Pollen-grains and Flowering Plants (Angiosperms).

IN a recent discussion (Linnean Society, January 21) on the relationship between Dr Hamshaw Thomas's new race of Jurassic fossil plants, the Caytoniales, and modern flowering plants, the challenge thrown out that winged pollen-grains are not to be found among existing Angiosperms was accepted, and the genus Sararanga (Pandanaceæ) was brought forward as possessing such. This appears to be incorrect The genus was founded by Hemsley in 1894 (*Journ. Linn. Soc.*, 30, 216) on the female flowers. Later the male flowers were described by Stapf in Hooker's "Icones Plantarum," 26 (1899), and the pollen-grain is there stated to be "ellipsoideis minute papillatis," and depicted so in a figure. There is no mention of wings (air-vesicles), nor are such shown in the drawing I have myself examined the pollen from dried material and have failed to find the least trace of anything of this nature. Besides the original species (*S. sinuosa*), one other has since been added to the genus, founded only on a fruiting specimen.

Being suddenly confronted with Sararanga, as I was making my statement that winged pollen-grains do not occur among existing Angiosperms, naturally prevented my making the point I intended, especially as the genus was then new to me. Possibly also it was unknown to nine-tenths of the audience, who might therefore have left with the impression that as both the Caytoniales and Sararanga had winged pollen-grains, this feature in common favoured some affinity between them, and strengthened the supposed relationship between this new fossil group and the flowering plants generally. Hence this letter.

As the challenge is still open, my point might still bear statement The probable possession of winged pollen-grains (microspores) by the Caytoniales indicates this race of plants as having been wind-pollinated (anemophilous). Dr. Thomas, assuming on other grounds that there is an affinity between the two races of plants, argues from these winged pollen-grains that the primitive Angiosperms could not have been insect-pollinated (entomophilous). How is it, then, that such supposed primitively anemophilous Angiosperms as the Screw Pines (Pandanaceæ) and the catkin-bearing families (Amentiferæ) have not retained this efficient mechanism for the conveyance of pollen through the air? On the view held by the writer that all existing flowering plants were probably descended from entomophilous stock, and that where anemophily occurs it is derivative and not primitive as in Gymnosperms, the absence of winged pollen-grains is understandable. Perhaps geologically there has not yet been time for their evolution, even in those forms, such as some of the Amentiferæ, which were probably among the earliest to substitute anemophily for entomophily.

At the meeting, stress was laid on the resemblance between the male panicle of Sararanga and Antholithus, the probable microsporophyll of the Caytoniales. This, however, can only be superficial, unless our morphological conceptions are at fault; for we are attempting to compare a shoot-structure (inflorescence) with a leaf-structure (a sporophyll or part of one). The resemblance is also strong between the individual tuft of microspore-bearing bodies of Antholithus and the male flower of Pandanus. This again can surely have no phylogenetic significance, for there is evidence that the unisexual flowers of the Pandanaceæ have been derived by reduction from hermaphrodite ones. In the male flower of Freycinetia, a genus belonging to this family, a rudimentary gynœcium is actually present.

The Leaping Salmon.

DR. DAVID STARR JORDAN's letter in NATURE of January 16 induces me to send a photograph which excels, I think, even that to which he refers Its beauty lies in the fact that the markings on the fish, its eye, and even its mouth, are clearly visible; in all other photographs of leaping salmon which I have seen, the fish has been a mere silhouette.

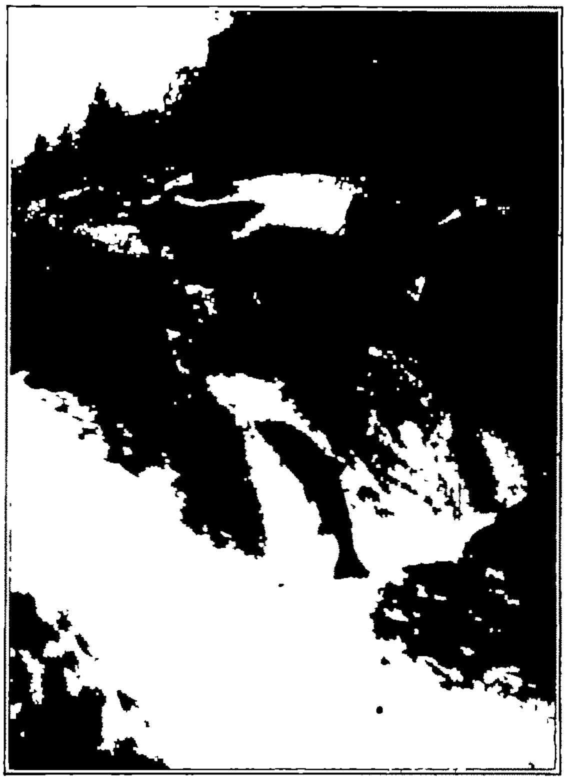

FIG. 1.

The photograph was taken at the well-known "Salmon Leap" on the River Garry at Struan, Perthshire, in August 1924. The fall is some twelve feet high, and it was an evening when the water was fairly full and the salmon were particularly lively in their efforts to scale the fall. It is possible, by scrambling down over the rocks, to get quite close to the water, and we were rather wetter than was comfortable by the time our exposures—three in all—were made. Of these, one showed a small fish, far away from the camera, one was utterly blank, and the third, here reproduced (Fig. 1), showed a fish of twenty to thirty pounds at a distance of about fifteen feet from the camera. This particular fish failed at this attempt, since it jumped more than high enough, but not far enough to reach the unbroken water above.

Often an ill-directed jump would result in a fish's striking its head against the bare rock with a crack which could be heard fifty yards off; it is a marvel to me that such a blow does not break the salmon's head, but it appears to be without effect, for they continue to come up undaunted.

The obtaining of a photograph such as this is always the accompaniment of a considerable amount of luck, and I account myself fortunate in having secured this one, which has been admired by many as a fine example of its kind.

Weather Prediction from Observation of Cloudlets.

SOME three years ago I had explained to me by an Irish land official, whose duties are largely carried out in the open air in South Kerry, a method of weather prediction which is much the same as that described in NATURE by Sir G. Archdall Reid. Attention was fixed on a small fragment of cloud, if the cloud increased in size, rain was to be expected within a few hours at most; if the cloud decreased, no rain was to be expected for some little time. I have had numerous opportunities of testing this method, and I do not recall any occasion on which the forecast made was not borne out by events.

The occasions on which my tests were made were all in unstable weather conditions of the kind in which, while hoping for a fair period, one nevertheless takes out a mackintosh to be on the safe side. These are doubtless the conditions referred to by Dr. Lockyer when he writes of "doubtful afternoons." The clouds observed were never cirro-cumuli, but always either small detached fragments of cumulus or fracto-stratus, commonly known as "scud," and at a height of, probably, not more than 3000 feet. It seems scarcely likely that in settled fine weather one would think of applying any test for imminent rain, but in such an event Capt. Cave's criticisms would no doubt be found to be well grounded. It seems possible that the differences between Sir Archdall Reid's and Capt. Cave's opinions in this matter may be due to Sir Archdall's regarding as a general method of prediction one which is applicable only in particular conditions, namely, those of showery uncertain weather, and, it may be, in particular localities; and also, to some extent, to the lack of precise definition of the type of cloud to be observed.

Polyploidy and Sex Chromosomes.

PROF. RUGGLES GATES introduces hybridity with chromosome incompatibility as a possible source of polyploid series in plant genera. In my note I deliberately refrained from referring to this theoretical possibility because neither in intrasectional crosses nor in the widest possible intersectional willow crosses known to me does the remotest approach to total chromosome incompatibility occur. Furthermore, in my opinion, such a state of affairs is not likely to arise, or to have arisen, in Salix hybrids.

Even if it were possible, other complications, which Prof. Gates seems to have overlooked, would ensue. Consider a cross between two diploid Salix species A and B, A supplying the male parent and B the female. Let the sex chromosomes of the former species be designated X and Y and of the latter X' and Y', then, so far as the sex chromosomes are concerned, the male of A is of composition XY, and the female of B of build $X'X'$. It follows, therefore, that the hybrid males will have a sex chromosome formula of $X'Y$, and the hybrid females the composition XX'. If no reduction division takes place in hybrid sporogenesis, as the hybridity theory of polyploidy demands, the F_2 generation, although tetraploid, will have the formula $X'X'XY$, and only one sex is developed!

Prof. Gates instances several cases (to which, as a result of my own researches, I could add others both in animals and plants) in which polyploidy has originated in experimental work, but in none of these is the real difficulty raised by the failure of the duplication of the sex chromosome complement in polyploid Salices met. By quoting from the work of my colleague Dr. Blackburn and myself ("A Preliminary Account of the Chromosomes and Chromosome Behaviour in the Salicaceæ," *Annals of Botany*, vol. 38, p. 361, 1924) on the cytology of Salix in which we found peculiar relationships in respect to chromosome size, and by postulating secondary changes, he simply emphasises my original statement that, by the discovery of only one pair of heterochromosomes in the males of polyploid willows, the origin of polyploidy is thrown open for further consideration.

In conclusion, whilst directing attention to the innocent-looking remarks on the transformation of sex chromosomes into autosomes, I venture to leave them, with their far-reaching implications, to provoke their own comments

Mutant Groups in Nature, *Gentiana campestris* var. *alba*.

PROF. JULIAN HUXLEY (NATURE, October 3, 1925, p 497) may be glad to know that his example of mutant white-flowered *Gentiana campestris* has its analogue in Zetland. There, on the slopes of Whiteness Voe, is a very large group of white-flowered specimens, outnumbering the normal form, and I saw several good-sized patches in the remote island of Balta. There is also a considerable group on the slopes of Ben Lawers and on Glen Lyon. I saw no intermediates, although in the Isle of Wight there is a large colony of white Origanum and intermediates which are also almost certainly crosses of the white and normal plants. One might add that I brought a single red-flowered *Kentranthus ruber* to my garden about twelve years ago; seedlings came up and they remained constant, but last summer a white-flowered plant appeared. However, there seems to be a permanence in the white-flowered *Gentiana campestris* and in the albino *Geranium Robertianum* which continues for many years. It was very noticeable on one side of the Brazen-face outside Funchal; there it evidently seeded down the hill-slope.

G. CLARIDGE DRUCE.

Optical Rotatory Dispersion.[1]

A TRIBUTE TO THE MEMORY OF BIOT (1774–1862).

By Prof. T. M. LOWRY, F.R.S.

LAST year, in Amsterdam and in Paris, we celebrated the jubilee of the foundation in 1874 of the science of stereo-chemistry. The year before, in Paris and in Strasbourg, the centenary of the birth in 1823 of Louis Pasteur was commemorated. This series of celebrations would be incomplete unless it covered also the 150th anniversary of the birth in 1774 of the French physicist, Jean Baptiste Biot. For, apart from Biot's pioneer work on optical rotatory power, there could have been no discovery of molecular dissymmetry by Pasteur; and, apart from the study of molecular dissymmetry, we should have known very little of "chemistry in space."

THE DISCOVERY OF ROTATORY DISPERSION.

One might have supposed that the discovery of optical activity would have preceded that of rotatory dispersion; that, after the rotation of the plane of polarised light had been discovered, further research would have shown that this rotation varied with the wave-length of the light. This, however, is the opposite to what actually happened, for it was the colours resulting from the unequal rotation of light of different wave-lengths by a plate of quartz that first attracted the attention of Arago (*Mém. Inst.*, 1811, 12, 93) and thus led to Biot's discovery of the laws of optical rotation.

In view of the fact that Biot was thus led to a knowledge of optical rotatory power through a study of the phenomena of rotatory dispersion, it is not surprising that he always included measurements of dispersion in his work on optically active substances. The example thus set would probably have been followed generally, but for the discovery in 1866 of the Bunsen burner. This device, which made it easy to produce monochromatic light of one colour, was fatal to the study of dispersion, since no other monochromatic light could be produced with equal ease. The custom therefore arose of measuring the optical rotatory power of organic compounds for one wave-length only; and even physical chemists, seeking to discover the influence of solvent, concentration, temperature or chemical constitution on rotatory power, were content to work with sodium light only, and thus to record a single point on a curve of unknown form. Biot, however, always recognised the supreme importance of dispersion in his studies of optical rotatory power, and this fact alone brings his work into closer relation with the researches of the twentieth century than with those of the nineteenth.

THE LAW OF INVERSE SQUARES.

In his first memoir (*Mém. Inst.*, 1812, 1, 1-372) Biot only recorded the fact that the rotations produced by a plate of quartz decreased progressively with change of colour from violet to red (pp. 256-257). In his second memoir (*Mém. Acad. Sci.*, 1817, 2, 41-136), however, he undertook a more exact "Recherche de la loi des rotations des différens rayons simples dans le cristal de roche," and as a result he was able to announce immediately his well-known Law of Inverse Squares, $\alpha = k/\lambda^2$. For this law Biot was able to claim that "si elle n'est pas la loi de la nature elle en approche du moins assez pour pouvoir lui être substituée dans toutes les observations" (p. 85). It is noteworthy that Biot arrived at this important law in spite of the fact that he had no source of monochromatic light, and that his only wave-lengths were Newton's values for the boundaries of the different colours.

Special interest attaches to the graphical method which Biot used in order to express his Law of Inverse Squares. For this purpose Biot plotted along a horizontal axis the square of the wave-length of the light, and in a vertical direction the thickness of the plates of quartz required to produce rotations of 180°, 360°, 540°, etc., in light of a given colour. The law of inverse squares was verified (i) by a linear relation between $1/\alpha$ and λ^2, (ii) by noticing that the line passed through the origin, *i.e.* that on extrapolation to $\lambda^2 = 0$, $1/\alpha$ became 0 also, and α became infinite.

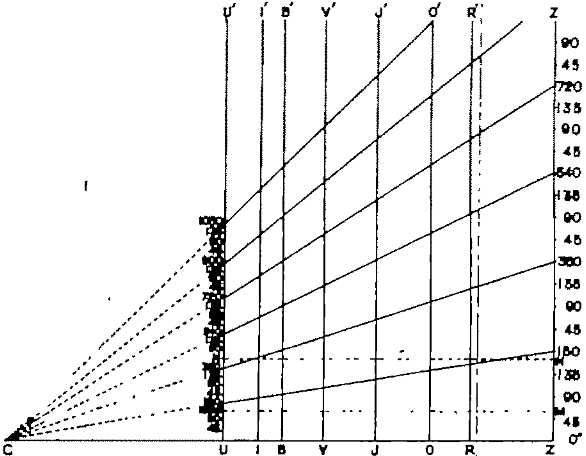

FIG. 1.—Biot's linear diagram. This diagram, in which the reciprocal of the rotatory power of quartz is plotted against the square of the wave-length of the light, is of the same type as those now used in the graphical method of testing for "simple rotatory dispersion."

Having established the law of inverse squares for quartz, Biot at once proceeded to apply it to those liquids in which he had just discovered the existence of optical rotatory power, and in particular to oil of turpentine (pp. 91-103), and to an aqueous solution of cane-sugar (pp. 103-114). The method adopted was to balance the rotation of the liquid against that of quartz plates selected so as to produce an equal and opposite rotation in the light transmitted through a piece of deep red glass. In each case the compensation appeared to be exact, proving that the law of inverse squares applied just as well to the liquid as to the rock crystal. Some years later, however, when trying to compensate lævorotatory turpentine against a dextrorotatory oil of lemon, either in separate tubes or mixed, Biot observed "une compensation très approchée, mais non pas complète, ni surtout générale pour tous les rayons" (*Comptes rendus*, 1836, 2, pp. 542 and 543). A very exact compensation was obtained when cane-sugar and invert-sugar were balanced against one another (*Ann. Chim. Phys.*, 1844, 10, 35), but the experiments with turpentine and oil of lemon proved clearly that the law of inverse squares was not exactly and universally true

---

[1] From a lecture delivered before the Société de Chimie Physique, in Paris, on December 9, 1925.

What then must be done in order to find the exact law of rotatory dispersion? Biot had the key in his own hands, and could have solved the problem with certainty if the experimental methods then available had provided data of sufficient exactness for a rigid test of the law. Thus, it is only necessary to plot $1/\alpha$ against λ^2 for a series of optically-active compounds, in order to discover that there is often an exact linear relationship between these two quantities. The straight line does not pass, however, through the origin at $\lambda^2 = 0$, but intersects the axis of zero rotation at a finite distance from the origin, *e.g* at a point given by $\lambda^2 = \lambda_0^2$. The true law of rotatory dispersion is therefore not $\alpha = k/\lambda^2$, but $\alpha = k/(\lambda^2 - \lambda_0^2)$.

It is a remarkable fact that, although Biot discovered the law of inverse squares in 1818, and discovered the errors in the law in 1836, it was not until about 1898 that Drude, as a result of a long theoretical inquiry, first enunciated the true law of rotatory dispersion in the general form $\alpha = \Sigma\frac{k_n}{\lambda^2 - \lambda_n^2}$; and even then several years elapsed before it was first shown, in 1913, that the general equation (which Drude had applied only in the case of quartz) could be used in its simplest possible form in order to express the rotatory dispersion of a large range of simple organic compounds (Lowry and Dickson, *Journ Chem. Soc.*, 1913, 103, 1067). If later workers had possessed Biot's peculiar mathematical genius, as well as his experimental skill, this law would surely have been discovered and verified nearly half a century earlier.

THE DISCOVERY OF ANOMALOUS ROTATORY DISPERSION.

The first reference to the optical rotatory power of tartaric acid is contained in a "Mémoire sur la polarisation circulaire et sur ses applications à la chimie organique" (*Mém. Acad.*, 1835, 13, 39-175). At the conclusion of a list of optically-active oils and syrups, it is recorded that a certain solution of tartaric acid gave a rotation of +8·5° for white light, and that the rotation was "plus forte sur les rayons les moins réfrangibles" The memoir itself, which records in a "note additionnelle" the important discovery of the inversion of cane-sugar (pp. 174-175), does not appear to contain any reference to this entry in the table; but three years later, Biot presented to the Academy a long memoir (*Mém. Acad. Sci.*, 1838, 15, 93-279) devoted entirely to the study of the rotatory power of tartaric acid under different conditions. In this memoir, stress was laid on the fact that tartaric acid was almost unique in its failure to obey the law of inverse squares. The existence of a *maximum rotatory power* for green light was indicated in a table (p. 236), which shows the rotation for light of different colours of a solution containing 34·27 per cent. by weight of tartaric acid. The memoir also contains a clear prediction of the existence of a second form of anomaly, namely, a *reversal of sign*, as indicated by the fact that the limiting values for 0 per cent. of water were negative for low temperatures and for short wave-lengths. This prediction was fulfilled when Biot, in 1850, found a negative rotation in the cold, glassy, anhydrous acid (*Ann. Chim. Phys.*, 1850, 28, 353) The more elaborate work of Bruhat (*Trans. Faraday Soc.*, 1914, 10, 89) has shown that, under these conditions, negative rotations are observed at 15° C. for all wave-lengths less than 5600 Å.U. Negative rotations have also been observed repeatedly in subsequent years, especially in concentrated solutions, and for light of short wave-length (see especially Lowry and Austin, *Phil. Trans.*, 1921, A, 222, p. 280).

SIMPLE AND COMPLEX DISPERSION.

Biot divided optically-active substances into two classes: (i) those which obeyed, at least approximately, the Law of Inverse Squares, (ii) those which made no pretence of obeying it. In the latter class he included tartaric acid, whilst its salts were included in the former class.

These two classes are now generally described as showing *normal* and *anomalous* rotatory dispersion respectively. The distinction between them depends on whether the dispersion-curve remains on the same side of the axis throughout the region of transparency (so that α, $d\alpha/d\lambda$, and $d^2\alpha/d\lambda^2$ are of constant sign), in which case the rotatory dispersion is *normal*, or whether it cuts the axis of zero rotation in the region of transparency, in which case the dispersion is *anomalous*. In the latter case the dispersion-curve exhibits all the well-known anomalies, *e.g.* an *inflexion*, *maximum* and *reversal of sign*; but, as these become less marked, they vanish successively into the infra-red region, where we have no means of following them experimentally. It is therefore impossible in many cases to decide whether a dispersion is really normal, or whether the dispersion-curve may be expected to cut the axis at some wave-length beyond the limit within which visual readings can now be made.

In my own work I have adopted Biot's original classification, with one essential modification, namely, that I have substituted the equation $\alpha = k/(\lambda^2 - \lambda_0^2)$ for Biot's Law $\alpha = k/\lambda^2$ Substances of which the rotatory power can be expressed by the equation $\alpha = k/(\lambda^2 - \lambda_0^2)$ are said to show *simple rotatory dispersion* (Lowry and Dickson, *Trans Faraday Soc.*, 1914, 10, 961; Lowry and Richards, *Journ Chem. Soc.*, 1924, 125, 2511), whilst substances which do not obey the law of simple rotatory dispersion are said to exhibit *complex rotatory dispersion* The difference between a simple and complex dispersion is seen most clearly in the ultra-violet region, where the course of the dispersion can be followed right up to the limit of transparency of the medium, within which alone the dispersion-equations are valid. I therefore prefer to retain, in this modified form, Biot's original method of classifying rotatory dispersions, according as they do or do not obey a certain law, rather than to be guided exclusively by the presence or absence in the visible spectrum of gross anomalies, such as an inflexion, maximum or reversal of sign

Although only a small correction is needed in order thus to convert Biot's law into the Law of Simple Rotatory Dispersion, this correction is of great importance, since if all optically-active substances obeyed the Law of Inverse Squares, all rotatory dispersions would be normal, and all would be identical with one another, *e.g.* $\alpha 4358/\alpha 5461 = (5461)^2/(4358)^2 = 1{\cdot}52$. The superposition of two normal dispersions, even if of opposite signs, would then always give rise to a normal dispersion of the same magnitude, and no form of anomalous rotatory dispersion could be developed by this process.

THE ORIGIN OF ANOMALOUS ROTATORY DISPERSION.

(*a*) *Anomalous Rotatory Dispersion produced by Optical Superposition.*—The secret of the origin of anomalous rotatory dispersion was disclosed by Biot in 1836, when he showed that ***anomalous rotatory dispersion can be produced in transparent media by the superposition of two normal rotations of opposite sign and of unequal dispersion.*** This superposition may be entirely optical, *i.e.* two independent columns of liquid may be balanced against one another by inserting them end to end in the same polarimeter; or the liquids may be mixed in the same tube. Both methods were used by Biot in compensating lævorotatory turpentine against dextrorotatory oil of lemon, in the experiments already described (*Compt. rend.*, 1836, 2, 543).

These two cases are easily understood, since the existence of two independent partial rotations of opposite sign can be demonstrated quite conclusively. Much more complicated are those cases in which a single optically-active compound, such as tartaric acid or α′-bromocamphor, gives rise to anomalous dispersion, since in these cases it is impossible to isolate from the medium a dextrorotatory and a lævorotatory component. Here again, however, a correct lead was given by Biot when he described his researches on the rotatory power of tartaric acid, under the title "Mémoire sur plusieurs points fondamentaux de mécanique chimique," since he evidently regarded the problem as fundamentally chemical and not merely physical in character.

(*b*) *Origin of Anomalous Rotatory Dispersion in Tartaric Acid.*—Biot's view that the changes of rotatory power which tartaric acid undergoes under the influence of bases, of boric acid, of water and of alcohol, are chemical in origin, was developed in a more concrete form by Arndtsen, who spent the summer of 1858 in working on rotatory polarisation in the laboratory of M. Verdet at the École Normale Supérieure.

To Arndtsen's view, that the anomalous rotatory dispersion of tartaric acid is due to the superposition of the opposite rotations of two interconvertible forms of the acid, I have given consistent support. In addition to making a careful study, during a period of more than twenty-five years, of the conditions under which a reversible isomeric change can take place in solution, I have proved (Lowry and Cutter, *Journ. Chem. Soc.*, 1925, 121, 532) that the anomalous rotatory dispersion at 20° C. of pure recrystallised ethyl tartrate can be expressed with perfect accuracy *as the sum of two simple partial rotations*, by means of the equation

$$[\alpha] = 20{\cdot}005/(\lambda^2 - 0{\cdot}03) - 20{\cdot}678/(\lambda^2 - 0{\cdot}056).$$

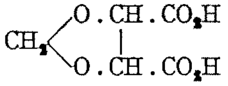
This dispersion is anomalous, and a simple calculation serves to locate the ***inflexion*** at 6950 Å.U., the ***maximum*** at 5630 Å.U., and the ***reversal of sign*** at 4245 Å.U. In the same way the rotatory power of a 50 per cent. solution of tartaric acid in water at 20° C. can be expressed (Lowry and Austin, *Phil. Trans.*, 1922, A, 222, p. 293) by the equation

$$[\alpha] = 17{\cdot}485/(\lambda^2 - 0{\cdot}03) - 12{\cdot}080/(\lambda^2 - 0{\cdot}074).$$

This dispersion is anomalous, like that of the ester, and calculation shows (in agreement with direct experiment) that the ***inflexion*** occurs at 6376 Å.U., the ***maximum*** at 5373 Å.U., and the ***reversal of sign*** at 4140 Å.U.

The latter equation is of interest because Longchambon (*Compt. rend.*, 1924, 178, 951; *Bull. Soc. fr. Min.*, 1922, 45, 161) has proved that solid tartaric acid is lævorotatory and has a "normal" dispersion. Moreover, it gives a dispersion-ratio $\alpha 4358/\alpha 5780 = 2{\cdot}14$, which agrees closely with the ratio 2·2 deduced ***for the negative partial rotation*** in the above equation (Lowry and Austin, NATURE, Sept. 20, 1924, 114, 430). There can, therefore, be little doubt that this negative partial rotation is due to the persistence in the solutions, as Biot postulated, of unchanged molecules of the solid acid, which Longchambon describes as α-tartaric acid. Conversely, the positive partial rotation in our equation can be attributed to the presence of the β-tartaric acid, which Longchambon supposes to be formed by a reversible chemical change from the α-acid, just as Biot postulated ninety years ago.

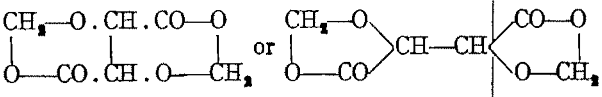
This view of the origin of the anomalous rotatory dispersion of tartaric acid is confirmed by the fact that it is possible to prepare dextrorotatory and lævorotatory derivatives of tartaric acid, the rotatory dispersions of which are not merely ***normal*** but ***simple***, like the two partial rotations of the above equations. Thus the rotatory power of ***methylene-tartaric acid***,



(Austin and Carpenter, *Journ. Chem. Soc.*, 1924, 125, 1939), can be expressed by the equation

$$[\alpha] = -24{\cdot}627/(\lambda^2 - 0{\cdot}0446),$$

whilst the rotatory power of ***dimethylene tartrate***,



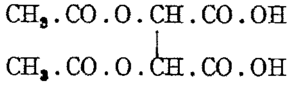
can be expressed (*ibid.* p. 1945) by the equation

$$[\alpha] = +34{\cdot}168/(\lambda^2 - 0{\cdot}03132).$$

There can be little doubt that the lævorotatory compound is a derivative of pure α-tartaric acid, whilst the dextrorotatory compound is a derivative of pure β-tartaric acid. This conclusion is confirmed by the fact that, although the dispersion constants are not identical with those of the two partial rotations in the above equations (which are themselves variable from compound to compound), the dextrorotatory compound has a smaller dispersion constant than the lævorotatory compound.

Exceptional interest attaches to the acetyl-derivatives. In this case, Austin and Park have shown

(*Journ. Chem. Soc.*, 1925, 127, 1926) that the rotatory power in dry acetone of *diacetyl-tartaric acid*,

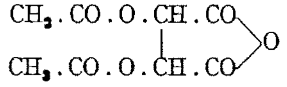


$$\begin{array}{l} CH_3.CO.O.CH.CO.OH \\ \qquad\qquad\quad | \\ CH_3.CO.O.CH.CO.OH \end{array}$$

can be expressed by the equation

$$[\alpha] = -6{\cdot}508/(\lambda^2 - 0{\cdot}0833).$$

In the same way the rotatory power in dry acetone of *diacetyl-tartaric anhydride*,



$$\begin{array}{l} CH_3.CO.O.CH.CO \\ \qquad\qquad\quad |\qquad\quad >O \\ CH_3.CO.O.CH.CO \end{array}$$

can be expressed by the equation

$$[\alpha] = +18{\cdot}354/(\lambda^2 - 0{\cdot}0507).$$

In this case again, therefore, the rotatory dispersion of the two derivatives is simple, and the dextrorotatory compound has the smaller dispersion constant. In wet acetone, however, the anhydride is not stable, and is gradually hydrolysed to *diacetyl-tartaric acid*. Since the rotations of the two compounds are opposite in sign, and their dispersion constants are of unequal magnitude, all the conditions necessary to produce anomalous dispersion are present in the solution. Thus, a freshly prepared solution of the anhydride, which gave a *simple dextrorotation*, soon showed a *complex and anomalous dispersion*, owing to the development in the free acid of a negative partial rotation with a high dispersion coefficient. This complex and anomalous dispersion was transformed in turn into a *complex and normal dispersion*, when the negative term had become predominant over the whole range of wave-lengths; and finally, when hydrolysis was complete, the solution showed only the *simple lævorotation* of the free acid (Austin and Park, *loc. cit.*). This case is of special importance, since it provides a working model of the mechanism postulated by Biot, by Arndtsen, and more recently by Longchambon, in order to account for the development of anomalous rotatory dispersion in solutions of the free acid.

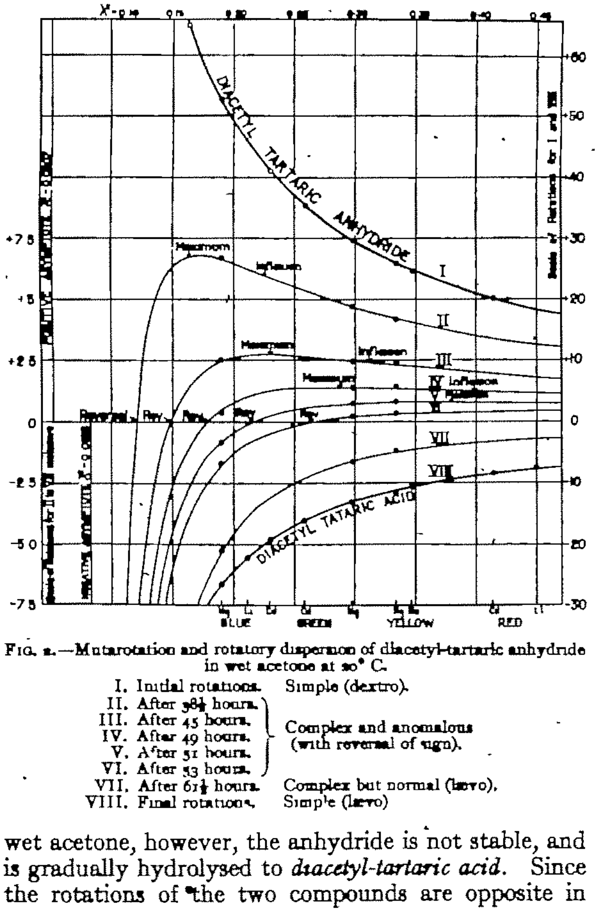


FIG. 2.—Mutarotation and rotatory dispersion of diacetyl-tartaric anhydride in wet acetone at 20° C.

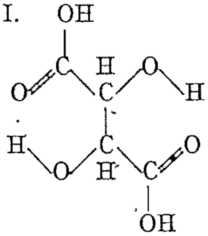
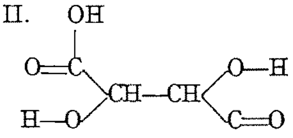
I.	Initial rotations.	Simple (dextro).
II.	After 38½ hours.	Complex and anomalous (with reversal of sign).
III.	After 45 hours.	
IV.	After 49 hours.	
V.	After 51 hours.	
VI.	After 53 hours.	
VII.	After 61½ hours.	Complex but normal (lævo).
VIII.	Final rotations.	Simple (lævo)

The ease of transformation of α into $\alpha \rightleftharpoons \beta$ tartaric acid suggests that the difference between the two compounds involves a rearrangement of structure which is even less drastic than a keto-enolic change. I therefore formed the opinion some years ago that the difference between the two forms of the acid might depend merely on an arrest, in two favoured positions, of the free rotation of the molecule about the single bond between the two central carbon atoms. The clear recognition of the bivalency of hydrogen (Lewis, "Valence," 1923, p. 109; Lowry and Burgess, *Journ. Chem. Soc.*, 1923, 123, p. 2111; Lowry, "Nouveaux aspects de la théorie de la valence," *Bull. Soc. Chim.*, 1924, p. 9) has, however, made it possible to assign to tartaric acid alternative formulæ I. and II. (Lowry and Austin, NATURE, 1924, 114, p. 431) which appear to fulfil all the essential conditions required for a graphical representation of the α- and β-tartaric acid of Longchambon. There is, however, not enough evidence available to show which of these formulæ should be assigned to α-tartaric acid and which to β-tartaric acid.

I.



II.



(*c*) *Origin of the Quasi-anomalous Rotatory Dispersion of Camphor.*—Although the rotatory dispersion of camphor is *normal*, it depends on the superposition of two partial rotations of opposite sign, and is therefore *quasi-anomalous* (Lowry and Cutter, *Journ. Chem. Soc.*, 1925, 127, p. 608). What, then, is the origin of these two opposite partial rotations? Tschugaeff has shown that anomalous rotatory dispersion can be produced by superposing the opposite partial rotations of two radicals in the same molecule, as in *l*-menthyl *d*-camphorsulphonate (*Trans. Faraday Soc.*, 1910, 10, 73). I have adopted this view in the case of camphor, with a novel assumption as to the nature of the asymmetric radicals. Thus I suppose that the high-frequency negative partial rotation of camphor is associated with the two saturated quadrivalent asymmetric carbon atoms. On the other hand, it is clear that the positive partial rotation, which is controlled by a dispersion constant corresponding approximately with the wave-length of the ketonic absorption-band (Lowry and Cutter, *Journ. Chem. Soc.*, 1925, 127, 611), is in some way linked up with the double bond of the $>C=O$ group. I have therefore suggested (Lowry and Walker, NATURE, April 19, 1924, 113, 565) that although a carbonyl radical in a symmetrical molecule possesses a plane of symmetry, this is no longer true in an unsymmetrical molecule. As evidence of this absence of symmetry, I have adduced the fact that camphor gives unequal yields of borneol and isoborneol on reduction, proving that the two links of the double bond are of unequal strength. It is, therefore, a mere unjustified analogy which has led to the assumption that the carbonyl-group of camphor is a symmetrical radical, and no further evidence is required to justify the view that the carbon atom of the ketonic group is in fact an asymmetric carbon atom, *i.e.* that it possesses an *induced asymmetry*, in view of the influence upon it of the *fixed asymmetry* of two of the saturated quadrivalent carbon atoms. This property of induced asymmetry appears to be very frequent in unsaturated optically-active compounds, and can be used in order to account for the presence of low-frequency partial rotations in many compounds in which the unsaturated group is not too far removed from the fixed asymmetric centres.

In this address I have presented an intimate mixture of Biot's researches with those of my colleagues of the present day. The fact that so intimate a blend is possible is in itself a tribute to the genius of Biot, whose work, although carried out with the mechanical equipment of the nineteenth century, was always conceived in the spirit of the twentieth century.

The American Bison: A Questionable Experiment.

By Dr. James Ritchie.

Thirty-eight years ago the sum total of American bison had been reduced from the millions of a century earlier to a number estimated by Hornaday at 1091, and there was a prospect that the species might become extinct. The situation was saved by the action of the Governments of the United States and of Canada, each of which placed remnants of the dwindling herds under protection in large reserved areas. The rapidity with which the protected animals recuperated is well illustrated by the history of the Canadian herd. In 1907 the Dominion Government, acting through the Department of the Interior, purchased the 709 members of the herd owned by Michael Pablo of Montana, which can be traced back to 4 wild calves captured by an Indian in 1873. By 1909 the Pablo herd had been set at large in the Buffalo National Park at Wainwright, an area 15 miles long and 13 miles wide, and in 1925 this herd was found to number approximately 12,000 head, the increase in sixteen years being about 11,300. The future of the species in Canada, therefore, seems to be assured. So far, the success of the experiment of protection has been all that could be desired.

A new difficulty now faced the authorities in Canada. The area of close on 200 square miles set aside for the original herd was insufficient to support the new numbers, and some method of reducing the numbers and of disposing of the annual increase had to be devised. Some 2000 have been slaughtered for food and robes, some have been transferred to other parks, including a pair sent to the Scottish Zoological Park in Edinburgh, and more than 1600 have been transported northward for 700 miles to Wood Buffalo Park in the North-West Territories. The Wainwright stock now reduced to about 8000, or about one to 16 acres, must be still near the food limit of the area (10 acres to one sheep is a rough guide to the food capacity of Scottish mountain pastures), but arrangements are being made for the disposal of the annual increase, which in the full herd amounted to 1500 individuals a year. It is, however, to the transference of large numbers to Wood Buffalo Park that attention is here particularly directed.

The Department of the Interior is to be congratulated on the success of the work of transference; for, by means of specially designed cars and barges, 1634 bison were moved by rail and water for 700 miles with only 8 casualties. But the transference gives rise to some doubt from the scientific point of view.

In Wood Buffalo Park there existed the only herd of wild bison which has survived, and these, the "wood buffalo," have been separated from the "plains buffalo" of the reserves as a distinct race, *Bison bison athabascæ*, characterised by its larger size, darker colour, more dense and silky hair, and larger and more incurved horns. Whether these characters are due to innate variation emphasised by segregation, or are simply the evidences of the effect of a different environment, is not known. At any rate, this race has now little likelihood of survival as a pure strain, for amongst its members, which probably do not exceed 1500 in number, have been deposited 1600 individuals of the contradistinctive race of the plains; and the wardens report that "the plains and the wood buffalo are mingling freely and that there is every prospect of the complete amalgamation of the two herds."

From the scientific point of view the opportunity of making an interesting experiment has been missed. Had the surplus plains buffaloes been deposited in an area similar in latitude, vegetation and climate to Wood Buffalo Park, but isolated from it, instead of in the Park itself, the wood buffalo race would have remained uncontaminated, and time would have shown whether in the new environment the plains buffalo would have assumed the distinctive characters of the wood buffalo. Had it turned out that these characters were wholly environmental, as they may well be, an interesting biological correlation would have been proved, and no objection could then have been taken to fortifying the wood buffalo herd by the addition of plains individuals.

In the meantime two suggestions may be made. First, in view of the possible swamping and disappearance of the distinctive wood buffalo as the result of crossing, it should be assured that several pure-bred typical specimens of that race find a place in one or more of the Dominion or other great museums. Secondly, if it be possible, the next batch of surplus plains buffaloes to be transferred from Wainwright should be placed in a northern area other than Wood Buffalo Park, with the view of establishing a new and independent herd in which the influence of climate might be watched. The result would finally condemn or vindicate the 1925 experiment of commingling the two racial forms.

Obituary.

MR. B. N. PEACH, F.R.S.

THE death of Benjamin Neeve Peach on January 29 has removed one of the most conspicuous figures from the Scottish geological world. Born in 1842, he had retired from the Geological Survey of Scotland in 1905, but advancing years and recurrent attacks of rheumatic gout did not prevent him from taking a keen interest in every kind of investigation and discovery in the fields of research which he had cultivated.

Peach was born in Gorran, Cornwall, and his father, Charles W. Peach, was a notable man, who, although a Customs officer of comparatively humble station, had trained himself in geology and biology until he was well known for his original contributions to natural science. He was the friend of Sir Roderick Murchison, Hugh Miller, Robert Dick, and many other eminent scientific workers. The boy attended school at Peterhead and Wick (Caithness) and passed on to the Royal School of Mines (London), where he studied under Huxley, Ramsay, and many of the first teachers and investigators of the time. Benjamin Peach entered the Geological Survey in due course, and after a short period of work in London with Salter, the palæontologist, started field work on the Scottish staff. His colleagues included such men as Archibald Geikie, James Geikie, John Young, and at a later date, W. Gunn and John Horne, men of brilliant ability who were destined to make their department famous by their researches. At their head were two great geologists, Sir Roderick Murchison and Sir Andrew Ramsay. Each of the group had his individual merits and claims, but Peach in some ways was the most brilliant of them all.

The love of biology, which Peach probably acquired from his father, was one of his principal interests. For many years he acted as palæontologist to the Geological Survey of Scotland and did a vast amount of routine work. His special field, however, was the fossil Crustacea, and on these he has left some short monographs and papers. He ascribed his interest in this group to the teaching of Huxley, and by his high artistic skill he was able to furnish all the drawings required to illustrate the memoirs.

It was as a field geologist, however, that Peach especially shone. His experience was vast, for there was scarcely a parish in Scotland in which he had not worked or visited at some period. His early work was in the Scottish Midland valley, where a great variety of rocks, sedimentary and igneous, lay open to his scrutiny, and the glacial and alluvial deposits were of great diversity and presented many problems then awaiting solution. In course of time he began work in the Highlands and was one of the leaders of that band who settled the obscure questions involved in the great thrust zones of the north-west. From there his work spread over many parts of that delightful but puzzling country. When Lapworth's discoveries in the Scottish Silurian rocks necessitated revision of the published maps, Peach and Horne undertook the work and carried it to completion with triumphant success.

Peach's wide experience of field work, however, was only one of the factors that contributed to his pre-eminence. Peach had in especial degree the gifts that make a great field geologist. With great physical strength and activity, he combined a restless passion for investigation that left no stone unturned that seemed likely to conceal some evidence. He had the most wonderful ingenuity and an imagination that amounted almost to inspiration. In difficult ground where the evidence was scanty and obscure, he tried every possible hypothesis and his judgment was seldom at fault. With these he had the rarest faculty of all, that of seeing in three dimensions, and in all sectional planes, the structural anatomy of the country he was mapping; so that each bit of evidence was fitted immediately into its place. No other geologist of his time had this faculty in the same measure except Charles Lapworth of Birmingham.

To his great gifts as a geologist were added the most charming personality and a striking physique. To his last days Peach had the boisterous spirits of a schoolboy. Full of humour and endowed with innumerable good stories, which he retailed in broad Scotch, he was a centre of attraction in every social gathering. His influence on young men was remarkable, and probably the greatest service he did to science was the training he gave to successive generations of young geologists, partly by precept (of which he was very lavish) but principally by example and by lessons in the field. To accompany Peach for a few weeks in the field (in the Highlands especially) was a liberal education for a young geologist; and by his rich store of recollected facts, his penetrating acuteness in observation, his rapid and logical deductions, and the lightning-like rapidity with which he read the riddles of geological structure, he inspired his assistants with a love of the work and a knowledge of the best and most rapid methods of getting accurate results. It was not easy going, for Peach made each field day an arduous task, both physical and mental, but the reward was certain.

In the study and the office Peach was a different man. His knowledge of geological cartography was profound, and his drawings, sketches, sections and maps were never at fault and were often of the greatest merit. As a writer, however, he was less successful. He hated the slow labour of the pen. Although fluent of speech, he was a slow and involved writer, and only by patient effort could he express his thoughts in clear sequence and exposition. Fortunately, however, his defects were more than compensated by the great literary skill of his friend and colleague Dr. John Horne, who formed with Peach a partnership that produced many geological monographs now known as classics in every country where geology is studied. Ably supported by their colleagues, these two geologists achieved magnificent results in many fields of geological work. Their faculties blended so perfectly that each produced his best in their joint enterprises, and they have dominated the progress of Scottish geology for the last forty years.

The list of geological papers, monographs, and memoirs to which Peach contributed is a very long one, but they mark only a portion of his activities. His published maps and the manuscript maps that show his field results are to the initiated even more instructive. Such work, for example, as his survey of parts of Assynt, of Arthur's Seat, and of the graptolite zones of the south of Scotland, indicates the hand of the master. For many years he gave devoted service to the geological mapping of Scotland, and so long as men take interest in Scottish geology his memory will endure.

J. S F.

DR. W. E. HOYLE.

THE death of William Evans Hoyle, D.Sc. (Oxon.), on February 7, at Porthcawl, has removed from this world one who, to the deep regret of his many friends, had for the last year or two been compelled by ill-health to withdraw entirely from that active participation in their pursuits to which for half a century they had been accustomed.

Born at Manchester, in 1855, Hoyle was by circumstances inclined to the profession of his father, William Jennings Hoyle, an engineer connected with both Whitworth's and Armstrong's. But his education at Owens College and afterwards at Oxford, which he entered as an exhibitioner in natural science at Exeter College, being elected later a junior student of Christ Church, turned his thoughts to the mechanism of the animal body, and this attraction was intensified by the influence of the great teacher, Rolleston. Thus it was that, after taking a first class in natural science, and qualifying at St. Bartholomew's Hospital for M.R.C.S., Hoyle was glad to become demonstrator in anatomy at Owens College and, not long after, to migrate to Edinburgh as a naturalist on the editorial staff of the *Challenger* Expedition. This division of interests bore at first similarly divided fruit: the year 1883 saw papers by him on primary epithelioma of the lung and on a new species of Octopus, while 1886 produced his translation of Leuckart's "Parasites of Man" as well as his report on the Cephalopoda collected by the *Challenger*. After this it was the cephalopods that conquered; on that fascinating group Hoyle produced a series of reports and papers, including reports on the cephalopods collected by Herdman at Ceylon (1904), by Stanley Gardiner at the Maldives and Laccadives (1905), by the National Antarctic Expedition (1907), and the Scottish National Antarctic Expedition (1912). Valuable and thorough though they were, these works did not introduce any startling changes in our conception of the group; apart from the systematic aspect, the chief study to which they led was that of phosphorescence in the cephalopods and other animals of the deep sea. Hoyle's knowledge of recent cephalopods was summarised in his presidential address to Section D of the British Association at Leicester (1907).

Meanwhile his systematic work and his training in the *Challenger* Office had qualified Hoyle to act as curator of a large collection. A chance arose for transferring him to the Zoological Department of the British Museum, but failed owing to the opposition of the staff, which did not like to see promotion checked by the appointment of senior men from outside. There was, I know well, no objection on personal grounds. The result, whether gain or loss to the British Museum, was a gain to Hoyle's own development and to the museum world. What London rejected, Manchester seized: Hoyle was made curator of the Manchester Museum, at Owens College, and, under the guidance of Sir William Boyd Dawkins, entered on his career as a great museum curator and administrator. He studied his new profession, as all museum-men should do, from every side. Methods of exhibition, of conservation, of storage and arrangement, of registration, and of card-indexing, all benefited from his active mind He even trespassed on the field of the librarian, and was, I believe, the first in England to apply the Dewey decimal system, which he used in his catalogues of the libraries at the museum and the Conchological Society All the results of his museum experience were communicated by him to the Museums Association, of which he was an original member, becoming its president in 1906. At the yearly gatherings of that body, as in all meetings of zoologists, his sagacity and his humour were alike welcome.

When, in 1909, a National Museum was to be established for Wales, the governors took the unprecedentedly wise step of first getting a director. Hoyle was their choice, a fact which he jestingly ascribed less to his own merits than to his name "Evans." On his own suggestion, he was at once sent abroad to complete his already extensive knowledge of the great museums. The plans were drawn to his specification and emended after criticism by himself and an independent expert. To the wisdom of the governors in trusting to Hoyle's initiative and direction is due the high position of that Museum to-day. We all regretted that he should have had to retire before receiving public acknowledgment of his great services.

F. A. BATHER.

WE regret to announce the following deaths:

Prof. D. S. Capper, from 1902 until 1921 professor of engineering at King's College, London, on February 12, aged sixty-one years.

Prof. W. O. Crosby, emeritus professor of geology in the Massachusetts Institute of Technology, known for his work on ore deposits and on the geology of the Boston Basin, Alaska, and the Rocky Mountains, on December 31, aged seventy-five years.

Prof. F. Y. Edgeworth, fellow of All Souls College and emeritus professor of political economy in the University of Oxford, president in 1912–14 of the Royal Statistical Society, and joint editor for many years of the *Economic Journal*, the organ of the Royal Economic Society, on February 13, aged eighty-one years.

Dr. Ernst Ehlers, professor of zoology since 1874 in the University of Göttingen, on December 31, aged ninety years.

Dr. Sigmund Exner, emeritus professor of physiology in the University of Vienna, and a member of the Vienna Academy of Sciences, on February 6, aged eighty years.

Prof. J F Gemmill, F.R.S., professor of natural history, University College, Dundee (University of St. Andrews), and first president of the parent society of the Scottish Marine Biological Association, on February 10.

Sir John Burchmore Harrison, Director of the Department of Science and Agriculture, in British Guiana, the author of numerous papers on the chemistry of tropical products, on February 8, aged sixty-nine years.

Sir George Holmes, K.C.B., K.C.V.O., honorary member and for more than twenty years secretary of the Institution of Naval Architects, on February 13, aged seventy-seven years.

News and Views.

AN interesting address, which we hope to publish next week, upon Prof. Einstein's researches on relativity and the theory of gravitation, was delivered at the annual general meeting of the Royal Astronomical Society on February 12, by the president, Dr J. H. Jeans. The gold medal of the Society, which was awarded by the Council to Prof. Einstein, was handed to the foreign secretary, Prof. H H. Turner, for transmission to him; and with it, remarked Dr. Jeans, went "the most cordial wish of the whole Society that the future may bring with it health, vigour and further scientific triumphs of the kind that have already made him one of the outstanding figures of modern science; and I think we may anticipate the verdict of posterity and add, one of the outstanding figures also in the history of human thought." The following translation of a letter from Prof. Einstein, acknowledging the award of the medal, was read to the meeting: "He who discovers a line of thought which permits us to penetrate even a little deeper into the eternal mystery of Nature, is greatly privileged. He who, in addition, is encouraged by recognition, sympathy and help from the best minds of his time, experiences more happiness than any one can realise. In this spirit I thank you from the bottom of my heart for the great honour of which you have found me worthy. I should have wished to come to you in person to receive the gold medal, but unfortunately it is impossible for me to do so"

IT is announced by the Foreign Office that Dr. Hu Shih, Dr. V. K Ting, and Dr. C C Wang have accepted the invitation of Sir Austen Chamberlain to serve as Chinese members of the committee which is to advise the Foreign Secretary as to the utilisation of the funds of the Boxer Indemnity Two of these appointments are in accordance with a provision of the China Indemnity Application Act that at least two members of the advisory committee shall be Chinese; the third fills a vacancy created by the death of Sir John Jordan, and follows a decision that it was desirable to increase the Chinese membership Each of the three newly appointed members has had a distinguished career. Dr. Hu Shih, now professor of philosophy and English at Peking, was educated at Cornell and Columbia; Dr. V K. Ting, who is general manager of the Peipiao Coal Mining Co. and honorary director of the Chinese Geological Survey, studied at Cambridge, Glasgow, and Freiburg; while Dr. Wang, after graduating at Yale as a civil engineer, became closely associated with Chinese railway development and administration and has interested himself in various philanthropic and social movements.

THE announcement of these additions to the membership of the advisory committee should go some way towards reassuring Chinese opinion as to the *bona fides* and goodwill of the British people. The reasons for the continued hostility and distrust of the Chinese towards 'foreigners,' particularly as represented by the British, are temperately set forth by Mr. Frederic Anson in the February issue of the *Fortnightly Review* in an article entitled "The Chinese Point of View." Mr. Anson points out that this intense suspicion of everything foreign is due to the fact that a tranquil and exclusive nation has had forced on it from without a western organisation which has made its influence felt, not only in the Treaty Ports, but also in every province, and that owing to the principle of extra-territoriality, this influence is entirely beyond Chinese control. This principle has been, and is, applied rigidly without adaptation or flexibility as China shows signs of development and progress. Further, the students sent abroad to study western civilisation, on their return, finding no prospect in native enterprises, turn to business openings under foreign management; but they find themselves handicapped as against foreigners, often their inferiors in capacity; while they are entirely debarred from social intercourse owing to racial prejudice. It is, therefore, scarcely remarkable that the Chinese regard the foreigner as mainly aiming at exploitation pure and simple. Mr. Anson's article as a whole enforces the need for such a sympathetic understanding of Chinese character and culture in those who have dealings with them as can only result from close study from what, for lack of a better term, can only be called the anthropological point of view.

A PROVISIONAL committee has been appointed to draft the constitution of a society within the University of London for promoting interest in the welfare of animals, Capt. C. W. Hume, of Birkbeck College, being appointed secretary. This step was taken at a meeting held at Birkbeck College on February 12, after a lecture by Capt Fergus MacCunn, assistant secretary of the Royal Society for the Prevention of Cruelty to Animals. The lecturer stated that while a certain amount of prosecution is unfortunately unavoidable at present, some 4000 persons being convicted annually of the grosser forms of cruelty, infinitely more reliance is placed on the educational weapon, and in order to improve its efficiency the advice and co-operation of the educational profession is earnestly desired by the Society. Should the present movement become established in the University of London, efforts will be made to extend it to other centres of learning. Interesting features of the Society's work to which reference was made included (*a*) the holding of prize essay competitions, for which nearly 1,000,000 children compete annually; (*b*) the horse purchase scheme, whereby the services of a veterinary surgeon are provided free of charge to any ex-service man who requires to buy a horse; (*c*) the offer of a prize of 200*l*. for the design of a humane rabbit trap, no really satisfactory design having yet appeared; and (*d*) the humane destruction, at one centre alone, of nearly 60,000 stray cats and dogs, many of which might have proved a source of danger to human health.

IN his discourse delivered at the Royal Institution on February 12 on "Red and Blue Colouring Matters of Flowers," Prof. R Robinson said that the work of Willstatter showed that the anthocyanin pigments of flowers, fruits, and blossoms are substances which form differently coloured salts with acids and with bases. Thus many different shades may be produced by variations of the acidity or alkalinity of the cell-sap alone The molecules of all the anthocyan pigments contain the same fundamental nucleus (with 15 carbon atoms), distributed round which various atomic groupings may be attached in eleven different positions A sugar always occupies one of these positions and may be detached by the action of boiling aqueous acid. The pigment, transformed by loss of its combined sugar, retains its original colour and is now called an anthocyanidin All the known anthocyanins can be ultimately degraded to one of three fundamental anthocyanidins, all of which have been prepared artificially The Indians of Central America in the vicinity of the Orinoco prepare a red pigment called 'carajura' or 'chica' from a species of bushrope. This contains the characteristic nucleus of the anthocyanidins, so apparently carajura proclaims a fourth anthocyanidin. The pigments of flowers are of very little interest to the dyer, since the colours are evanescent Nevertheless, many of the most beautiful of artificial colouring matters, for example, the unsurpassed rhodamines, possess very similar central, tinctorial molecular groupings

ACCORDING to an announcement which appeared in the *Times* of February 15, Mr. John D Rockefeller, Jr, has offered to King Fuad and the Egyptian people the sum of 10,000,000 dollars (2,000,000*l*.) for the purpose of building and maintaining a new museum in Cairo and, in conjunction with it, an archæological institute to be housed in a separate building The offer was recently conveyed to King Fuad by Prof. James H. Breasted, the well-known Egyptologist of the University of Chicago, who has been appointed by Mr. Rockefeller to act as a member of the Board of Trustees of the Fund, of which the other members are Mr Everit Macy and Mr. Raymond B. Fosdick, both of New York It is intended that the new museum and institute should work in co-operation with the Egyptian Service des Antiquités. Details of the arrangements of the offer are to be discussed by representatives of the Egyptian Government and of Mr. Rockefeller at an early date This munificent gift, which is said to be the largest amount ever offered in a single sum for the promotion of humanistic studies, will be of inestimable value both to the investigation of Egyptian culture and civilisation and to archæology at large It has long been impossible to display the mass of material which has been gathered from the various excavations in Egypt in a manner adequate to the needs of students. The increase in space in a museum fully equipped on modern lines with material for the preservation of specimens, and adequately staffed with trained officers working in conjunction with the neighbouring archæological institute, will provide a stimulus to research of which the effect is difficult to estimate fully on this first announcement.

THE sessional programme for 1925–26 of the Institut d'Ethnologie and the Facultés et Établissements publics d'Enseignement supérieur of the University of Paris makes liberal provision for courses of instruction in the various branches of ethnology with special reference to the French colonial possessions. At the Institut, descriptive ethnography and descriptive linguistics are covered by M Marcel Mauss and M. Marcel Cohen respectively. M. M Delafosse lectures on the linguistics and ethnography of Africa, and M Jean Przyluski on the ethnography and linguistics of Eastern Asia and Oceania. Among the lectures to be given under the Faculties of the University are courses on the races of the French colonies by Dr. R. Verneau, the customs of Madagascar by M. Julien, the customs of French West Africa by M Delafosse, moral, religious and family rites in Australia and in the Sudan and Nigeria by M. Mauss, Indo-Chinese religions by M. Przyluski, and on the social, family and religious organisation of the Moslems by Prof. Doutté, Mahommedan law being also covered in a course by Prof. Morand. In sociology a general course is given by M. Fauconnet, and Prof. Cabaton will deal with the geography, history and institutions of Indo-China M. Brunhes, in the department of human geography, deals with "The Problem of the Pacific." In linguistics, provision is made for instruction in the languages of practically all the native populations of the French possessions, including Arabic, Berber, the Sudanese languages, modern Indian, Malagasy, Malay, Siamese, Annamese and Cambodian.

THE fifth annual report of the British Electrical and Allied Industries Research Association, which was presented at the annual meeting of the Association on February 12, is instructive and interesting The period covered was the end of the five years' agreement with the Department of Scientific and Industrial Research As the grants guaranteed by the Department are now on a diminishing scale, the Association has to look to other sources for enlarged contributions. The minimum requirements for the year are 16,000*l*, of which the Department pays 8000*l*., but five years ahead it will only pay 1600*l*. There are a very large number of committees, and representatives of all the interests concerned are present at the meetings. The Department appointed a committee to examine the work in progress, which has reported favourably. In particular it commended the work done on the phenomena of switching, arcing, and insulation. Although it was thought that the Association should not build a laboratory of its own in which to carry out all the investigations, yet in the opinion of the committee it might usefully supplement existing facilities, like the National Physical Laboratory, by the provision of a small laboratory for preliminary researches. The Association acts as a clearing-house for problems of common interest to the whole industry. It is also a great stimulus to the application of scientific methods in commerce. It has to be remembered, however, that an association of this kind does not obviate the necessity of research in pure science. It should and does act as an incentive to individual research. It is this latter kind of research which is in the greatest need of encouragement. We are glad to read that Prof. H. L. Callendar has extended his steam turbine researches to cover temperatures and pressures of 850° F. and 1500 lb. per sq. in. respectively, novel methods having been invented to cope with the experimental difficulties. Mr. Ll. B. Atkinson has been re-elected chairman of the Association, and at the luncheon which followed the annual meeting, he gave an inspiring address on British contributions to the world's progress in science and invention.

IN a paper by G. H. Farnes published in the *Wireless Engineer* for February, some remarkable phenomena observed in high-powered transmitting radio stations are described. In a large commercial station during alterations to the room housing the aerial inductance, it was found necessary to erect a temporary wooden wall. One day this became damp and consequently was slightly conducting. The high frequency currents induced in it by the currents in the coil caused it to heat up and ultimately burst into flame. On another occasion, three damp planks formed a triangle and the heating due to the eddy currents quickly set them on fire. The iron lock on the door is often unbearably hot due partly to hysteresis. A watch worn in the neighbourhood of the aerial is put out of order owing probably to magnetisation of the hair spring. This often happens in the neighbourhood of a dynamo When the point of a pencil is held near a metallic object like the case of an instrument, a torrent of sparks sometimes ensues. On one occasion when two people in the room shook hands, a stream of sparks came from one hand to the other. Out-of-doors the large porcelain strain insulators are sometimes found practically molten inside A portion of the barbed wire fence round the aerial site becomes so hot by the induced current that it cannot be touched, and sparks can be drawn from it by holding a piece of metal near it. A stay wire has been found red hot owing to the induced eddy currents. The top of a 460-foot high wooden lattice mast caught fire owing to sparking. As it cost 5000*l*., and if allowed to burn would close down the station, two firemen climbed up the mast by means of the diagonal bracing members and cut away the burning portions with their axes. Since Hertz's time these phenomena have often been observed on a small scale. We now have to guard against them in commercial undertakings

THE library co-operation movement initiated by the Association of University Teachers has gained momentum and made satisfactory progress during the past year. A large and steadily growing number of libraries of a university, learned, or specialist character in all parts of the British Isles have accepted, though in a few cases with reservations, the inter-library lending proposals put forward, and the increased facilities for research thus secured have already proved useful to investigators in many fields. The Joint Standing Committee on Library Co-operation appointed at last year's Conference has provided for as full as possible a utilisation of these facilities by setting up an Inquiry Office (located for the present in the University of Birmingham) which endeavours to discover copies of any publications required by research workers, and, if successful, reports whether they would be lent temporarily to the inquirer's library on the application of the librarian. Thanks mainly to the generosity of the Carnegie United Kingdom Trust, this information, though usually involving considerable clerical and postal expenses, can be supplied free of charge. There has been a steady increase in the stream of inquiries, and up to the present about seventy per cent. of the publications inquired for, though nearly all rare or foreign, have been reported as obtainable on loan from one or more British or Continental libraries. The compilation of a list of periodicals not included in the recently issued "World List of Scientific Periodicals" has also been begun. Though confined at present to periodicals in the possession of British libraries, and intended primarily to facilitate the work of the Inquiry Office, this list may eventually prove to have a wider usefulness. If published it would prove a valuable supplement to the existing World List.

To a series of articles in the *Forum* on the food resources of the world in relation to future wars, Mr. V. Stefansson contributes to the January issue a paper on Polar pastures. He estimates that of the 3,000,000,000 acres of land in the northern hemisphere that lie north of the region of possible wheat cultivation, the greater part is grazing land which is suitable for the reindeer and musk-ox or ovibos. He points to the successful breeding of the reindeer in Alaska, where, since the introduction of domesticated deer from Siberia between 1892 and 1902, the herds have been doubling every three years. The raising of musk-ox in reindeer lands would be practicable because the reindeer feeds on lichens in winter and uses grass only in summer, while the musk-ox eats grass all the year round. In the Arctic tundras the number of reindeer is limited by the winter food, which is only about one-tenth of the summer supply. This leaves scope for large herds of musk-ox. A use of the musk-ox in addition to the supply of meat would be for the production of fine wool, which has been proved to have the qualities of good merino. In addition it does not shrink. Mr. Stefansson estimates that the Arctic grasslands could support a hundred million reindeer and five times as many musk-ox with a total annual meat production of 55,000,000,000 pounds of meat

ACCORDING to the *News Bulletin of the U.S.S.R. Society of Cultural Relations*, a number of expeditions have been organised by the Russian Academy of Sciences and other scientific institutions, with the object of exploring the regions lying beyond the Polar circle in European and Asiatic Russia One of these expeditions was engaged in explorations of the northern section of the Ural Mountains, previously considered to be impassable. Rare specimens of plants and animals were collected. There were also indications of platinum deposits and petroleum in this region, and surface coal was found in the valley of the river Pechora. The polar expedition of the Academy has made a geological and geographical investigation of Novaya Zemlya Topographical charts were made for the first time in the central part of the Northern Island. The expedition discovered three uncharted lakes, and three new bays on the eastern part of the islands. Preparations are being made for an expedition to the Nicholas II. Land, discovered by Vilkinsky in 1913. This territory has hitherto remained entirely unexplored. An expedition under Prof. Gorodkov is exploring the tundra region between the estuaries of the rivers Ob and Yenisei. A commission sent to the Yakutsk territory for the purpose of ascertaining the amount of arable land available for colonisation found large tracts suitable for agriculture along the rivers Lena and Amga.

THE first number of a new Russian periodical, *Journal de Biologie et de Médecine expérimentales*, published by the State Scientific Institute of the Commissariat of Public Health in Moscow, has just been issued. The journal, which is of the type of *Pfluger's Archiv* and the *Zeitschrift fur die gesamte experimentelle Medizin*, is devoted to experimental works in physiology, general pathology, bio-chemistry, bio-physics, microbiology and allied sciences. The editorial committee, under the directorship of Prof. B. Sbarsky, consists of the following: A. Bach, P. Diatropoff, N. Koltzoff, P. Lazareff, L. Tarassevitch and M. Schaternikoff, with Prof. I. P. Pavlov as one of the chief collaborators. The main object of the journal is to unite in one publication the original works appearing in Russia and hitherto scattered amongst the special biological and medical periodicals, which appeared very irregularly and were frequently inaccessible to workers in allied branches of science. From the editorial notice it is seen that the new journal will appear in 8-9 fascicules per annum, the regular publication of which is apparently ensured. All the papers will be provided with summaries in English, French or German. The first number of the *Journal de Biologie et de Médicine expérimentales* contains nine papers dealing with various questions of immunology, bio-chemistry, bio-physics, experimental pathology, physiology, bacteriology and comparative psychology.

IF the present vogue for noticing centenaries does nothing more than to lead to inquiries into the history of industries, it will have served a good purpose. In mechanical engineering a century ago, Matthew Murray of Leeds occupied a prominent position. Few details of his life are at present available, but the centenary of his death is sure to lead to additions being made to these. He was born in 1765 and died near Leeds on February 20, 1826. He had then been in business with two partners as a steam-engine builder for thirty years, and his firm in 1812 built the four locomotives for Blenkinsop which were the first commercially successful engines of this type. George Stephenson did not construct his first engine until 1814. Murray is also known among engineers as the inventor of the locomotive slide valve, as a pioneer in the use of machine tools, as one of the advocates of steam navigation, and also as a keen rival of the famous old firm of Boulton and Watt.

IT is announced in *Science* that the Nichols Medal in chemistry for 1925 has been awarded by the New York Section of the American Chemical Society to Dr. Samuel Colville Lind, associate director of the U.S. Fixed Nitrogen Research Laboratory, Washington, for his work on "The Chemical Activation of Alpha Particles."

THE following officers of the Royal Astronomical Society were elected at the annual general meeting on February 12: *President*, Dr. J. H. Jeans; *Vice-Presidents*, Dr J. L. E. Dreyer, Sir Frank Dyson, Dr. J. W. L. Glaisher, and Rev. T. E. R. Phillips; *Treasurer*, Lieut.-Col. F. J. M. Stratton; *Secretaries*, Dr. Jackson, Royal Observatory, Greenwich, London, S.E.10, and Mr. H. Knox-Shaw, Radcliffe Observatory, Oxford.

AT the annual general meeting of the Optical Society, held at the Imperial College of Science on February 11, the following officers for the session 1926–1927 were appointed: *President*, Mr. T. Smith; *Vice-Presidents*, Inst.-Comdr. T. Y Baker, Mr. F. F. S. Bryson, Dr. R. S. Clay, Mr. H. H. Emsley; *Treasurer*, Major E. O. Henrici; *Secretaries*, Prof. Alan Pollard, Imperial College of Science, South Kensington, S.W.7, Mr. F. F. S. Bryson, 12 Oppidans Road, N.W.3.

BY the will of the Right Hon. Stephen Ronan, lately Lord Justice of Appeal in Ireland, who died on October 3 last, and left personal estate in England and the Irish Free State valued for probate at 83,907*l.*, the Medical Research Council will receive considerable benefits. After private bequests amounting to nearly 9000*l.* and numerous legacies to Irish charities, the residue is left to the Medical Research Council to be applied in assisting and promoting scientific research as the Council may think best, "but without limiting their discretion, I would wish that special attention should be given to the relief, cure, and prevention of physical pain by physical means."

THE following awards of the Institution of Petroleum Technologists have been announced: The Boverton Redwood Medal for sessions 1923–24 and 1924–25 to Mr. C. H. McCarthy-Jones, for his paper entitled "Electricity applied to the Winning of Crude Petroleum, with Special Reference to the Yenangyaung Field, Burma"; the Students' Medal and Prize for 1925 to Mr. Ernest Clark, Royal School of Mines, Imperial College of Science and Technology, for his paper entitled "Organic Theories of Oil Origin." The Institution's Scholarships for 1925 have been awarded as follows: Royal School of Mines, Imperial College of Science and Technology, London, Mr. J. O. Tanner; University of Birmingham, Mr C. J. Ward.

DR. HEM SINGH PRUTHI, in his letter on "Moulting of Insects" in NATURE of December 26, 1925, p. 938, recorded some experiments carried out on the common mealworm (*Tenebrio molitor*) which afford further evidence that moulting is not necessarily correlated with growth. Mr. C. Macnamara, Arnprior, Ontario, Canada, writes pointing out that Folsom and Welles in 1906, working on the Collembola, concluded that moulting is connected with excretion. The suggestion that the moulting of insects has other functions than providing for growth is recorded in the standard works on insects.

THE "Lopulco" system of powdered fuel firing is making progress in Great Britain. The North Metropolitan Electric Supply Co. will have shortly its new station at Brimsdown working on this system. There are five boilers, each of which has a heating surface of 11,000 square feet. The equipment includes the latest design of pulverising mills each of 15 tons per hour capacity, the making of which, together with the feeders, bunkers, separators, water screens, exhausters, etc., provides employment to many workmen at Barrow and Derby, where the Lopulco works are situated. Capt. Donaldson, the electrical engineer, is satisfied that the system will assure him high thermal efficiency with minimum maintenance and operating charges even from the lowest grades of fuel. As this station when complete will be the largest in the London area operating entirely with pulverised fuel, engineers are awaiting the results with much interest.

WITH the December issue, the *Journal of the Franklin Institute* completes one hundred years of uninterrupted publication, during which it has come to occupy an important position as an organ of the scientific world. Its purpose, that "of reporting to the community the activities of the Institute, and of disseminating knowledge of science and the arts," has enabled it to serve a wide range of readers. Commenting on the increasing specialisation of modern research, which has of necessity been reflected in the pages of the journal, the editors refer to the importance of communicating the multitudinous results obtained by scientific workers in justification of the step they are taking in making the journal the agency for the publication of researches carried out at the Bartol Research Foundation. Thus even more than formerly, the *Journal of the Franklin Institute* will be an organ for the publication of research, though its traditional regard for invention and matters of wide interest in science will be maintained.

APPLICATIONS are invited for the following appointments, on or before the date mentioned:—An assistant lecturer in zoology in the University of Birmingham—The Secretary (March 1). A laboratory assistant in the physics department of the Liverpool Collegiate School for Boys—Director of Education, 14 Sir Thomas Street, Liverpool. A science mistress at the County School for Girls, Gravesend—The Head Mistress.

Our Astronomical Column.

RECENT SUNSPOT ACTIVITY.—The first half of February has offered only very occasional opportunities for observing the sun. A photograph taken on February 5 showed the disc comparatively free from spots, but another taken on February 13 recorded nine or ten groups, including one visible to the naked eye. This spot is the chief of a procession of spots of recent origin, extending for nearly 25° of solar longitude. Details of it are as follows:

No.	Date on Disc, 1926.	Central Meridian Passage.	Latitude.	Area.
3	Feb. 9-21	Feb. 15·0	18° S.	1/1200

(Area expresses the proportion covered of the sun's hemisphere.)

One of the other spots elsewhere on the disc is the large recurring spot, in latitude 21° S., seen previously on the central meridian on December 25 and January 22. It is of regular outline and of about half its original size.

The great spot No. 2 (NATURE, January 30) has returned to the sun's visible disc, but is so much diminished that it is a telescopic object only.

COMETS.—An observation of Blathwayt's Comet was obtained on Feb. 8 by M. Chofardet at Besançon, which led to the following corrected elements:

T 1926, Jan. 3·12 U.T.
ω 328° 30′
Ω 136 5
i 128 22
log q 0·1293

EPHEMERIS FOR 0h.

A HOMERIC ECLIPSE.—The suggestion has been made many times that the passage in the 20th book of the Odyssey, where the seer Theoclymenus describes the sudden gloom and the disappearance of the sun, seems to indicate a total solar eclipse. But until now no one has considered it worth while to carry the matter further.

Dr. C. Schoch, in the *Observatory* for January, describes a research he has made, using Oppolzer's "Syzygien-tafeln" corrected by his own and Dr. Fotheringham's researches on ancient eclipses and occultations. He has examined all the eclipses of the twelfth century B.C., and finds that the only one total in Ithaca was that of April 16, 1178 B.C., total there at 11h 41m A.M. local time. This is five years earlier than the traditional date of the return of Odysseus, a very small discordance. The deduced date of the siege of Troy is 1198 to 1188 B.C. It would be unsafe to lay any great stress on this eclipse, since the poem is much later than the event; but it is extremely interesting to find that calculation supports the narrative, which makes it likely that the tradition used by Homer was not wholly mythical but had a substratum of fact. Dr. Schoch gives the dates in astronomical reckoning, but they are corrected here into civil reckoning.

Research Items.

Maori Agriculture.—Mr. Elsdon Best's valuable study of Maori cultivated plants and native methods of agriculture and attendant rituals and ceremonies has been published as *Dominion Museum Bulletin* No. 9 (Wellington, N.Z.). The Maori appear to have introduced at least five (and possibly six) food plants into New Zealand. These were not introduced by the first settlers; and it was the lack of the food plants of their earlier home as well as the greater difficulty in cultivating those which they did succeed in acclimatising that led them to the utilisation of the so-called fern-root, and exalted it to such an important position in their food supply that it was assigned a special mythical origin. Their principal food plant, however, was the *kumara* or sweet potato Special ceremonials were attached to every stage of its cultivation from planting to harvest Some of these, such as the ritual observed when a tuber of special size was found, recall the corn goddess customs of other countries A tradition, it is conjectured largely on philological grounds, suggests that the Polynesians may at one time have inhabited a country in which rice was the staple diet It is a curious fact that there is a double tradition of the origin of the *kumara*, one associating it with the deity Rongi, the other with the goddess Pani, who brought forth sweet potatoes *in the water*. In other elements in the Pani traditions, *kumara* is also connected with water, although it is a dry land plant. A transference of a rice tradition therefore appears not impossible.

Archæology of the Aleutian Islands.—A valuable monograph on the Aleutian Islands by Waldemar Jochelson has been published by the Carnegie Institution of Washington. It embodies the results of the archæological investigations on these Islands of the Riaboushinsky Expedition of 1909–10, on which the author was the leader of the anthropological section. The object of these investigations was to supplement the results of the Jesup Expedition of 1902 and endeavour to clear up the question of the ethnological affinities and origin of the Aleutians, upon which various views, none of them entirely satisfactory, were held. The anthropological division excavated a number of kitchen middens and house sites, finding many skeletal remains (about fifty were in a sufficiently good state of preservation to be available for measurement), and a large quantity of implements, in stone and bone, utensils, etc. Both geological and cultural conditions appear to preclude the hypothesis that the Aleutians represent a migration from the Asiatic continent. Their boats at the present day are not such as could have faced the lengthy and difficult sea voyage to which the geological conditions point. On the other hand, their language presents close affinities with that of the Eskimo. Their culture, which at the time they were first visited by the Russians still belonged to the Neolithic stage, contains some elements which are to be attributed to their environment, but with certain variations presents a close resemblance to that of the Eskimo; but it also includes elements which are related to the culture of the north-west coast of America Cranial measurements of the dead and living alike show a very high degree of brachycephaly —average 84, which suggests an Athapascan strain. The conclusion is that on the whole the evidence points to the Islands having been peopled from the American rather than the Asiatic continent.

A Mistaken Attribution in South American Linguistics.—We owe to the researches of Dr. Paul Rivet the correction of a mistake in American linguistics which has endured for nearly seventy years. In 1858 Ludewig in his "Study of American Aboriginal Languages" referred to a text in the Arda language which had been printed at Madrid in 1658. No ethnographical data are available relating to the Arda tribe, and the only fact known concerning it is that it lived between the upper waters of the Nanay, a tributary of the Amazon, and the Mazan, a tributary of the Napo. It was surrounded by the Yameo people on three sides and bounded on the north by the Zaparo tribe Dr. Rivet, who had devoted attention to this text, of which a copy is in the Library of San Isidro at Madrid, at intervals over a period of years, at last became suspicious as to its provenance, and submitted it to M. Maurice Delafosse, the well-known African authority. The result of M. Delafosse's examination is given by Dr. Rivet in the *Proceedings* of the twenty-first International Congress of Americanists held at Göteborg in 1924. The verdict is that the text in question is in pure Dahomean, and, except for a few phonetic variations possibly due to transcription, might well be contemporary. Portions of the text and the modern language printed in parallel columns place this conclusion beyond question. Further study has revealed that it belongs to the Popo dialect, and it is interesting to note that in date it is a hundred years earlier than any hitherto known specimen of the language of this part of Africa. It is clear, therefore, that the language of the Arda tribe can no longer be regarded as independent, as has been done on the evidence of this document; and the statement of Velasco that it belongs to the extinct dialects of Yameo, which had been abandoned as incorrect, must be reinstated.

Two Additions to the British Avifauna —In two recent issues of the *Scottish Naturalist*, Admiral J. H. Stenhouse describes two species of birds recorded for the first time from Britain Both arrived at Fair Isle, between the Orkney and Shetland Isles, during the autumn migration season of 1925, and this in spite of the fact that, during the period of the recorder's visit, weather favouring prolonged east to west migration was absent. The Petchora pipit, ***Anthus gustavi*** (Fair Isle, September 24), breeds in N.E. Russia and widely across northern Asia to Kamchatka, whence it generally moves south-east to China during the winter. It has not before been noted in Europe beyond Russia. Jerdon's reed-warbler, ***Acrocephalus agricola*** (Fair Isle, October 1), is a more southern bird, breeding in the Ural region and across Asia to the Himalayas. In winter it is found in India and north-west Africa. Apart from one record from Heligoland, it has not previously been found in western Europe. Both birds were far out of the normal migration track of their species.

The Medusæ of Norway —Dr. P. L. Kramp and Prof. D. Damas have published (*Vidensk. Medd. fra Dansk. naturh. Foren.*, Bd. 80, 1925) an account of the medusæ of Norway. The specimens on which the account is based have been collected from 1900 onwards, chiefly during cruises of the *Michael Sars* When the cruises of this vessel began, there were known with certainty only 17 species of medusæ in Norwegian waters, to which 10 were afterwards added through the work of E. T. Browne, and 7 more by Hj. Broch It was realised that with such an extended coast-line and numerous islands with deep water adjacent, providing a great variety of conditions, careful investigation would probably result in a considerable addition to the list of species; and so it has proved, for 57 species are now known, 19 of which are recorded from the area for the first time. The present account deals with the Hydrozoa—the Scyphozoa being reserved for a future part. Under each species is given a list of the stations at which examples were collected, notes on systematic characters, and in many cases on the geographical and bathymetrical distribution. Excellent figures are given of the new genus and of two new species, of some of the rarer species, and of aberrant examples.

Herring.—Mr. W. C. Hodgson gives us his second report on the work he has done in connexion with the herrings of the southern North Sea (Ministry of Agriculture and Fisheries, Fish Invest., Ser. ii. Vol. 8, No. 5, 1925. 6*s.* 6*d.*) From samples taken by the *George Bligh* and from records previously published by Bjerkan, immature herrings with one winter ring on their scales may be taken about the Dogger Bank, the Firth of Forth, and the Skagerak. Fish in their third year make their appearance in the commercial shoals, but, whilst some of these may become mature, it is not until the fish are a year older that they form the greater part of the catches made off the north-east coast, Northumberland to the Spurn, and high numbers come to maturity. With this and the statement that the younger fish are followed by older fish into the great fishery of the Southern Bight, and the finding of a considerable amount of spawning now on these grounds, Mr. Hodgson confirms a great deal of evidence which has been accumulated and interpreted by other workers. The presence in the shoals off the Northumberland coast in 1923 of large numbers of herrings with three growth zones on their scales and having a small first-year growth may be regarded as exceptional, and so may be the high percentage of fish of this age found in the catches from north-east of the Spurn in 1924. Negative evidence has been found for a migration of spents into the Channel from the Southern Bight, but a sample from north-west of Skagen indicates the possibility of a movement towards the Skagerak. The mixing of mature fish with first-year growths of 8 cm. and 9-11 cm. inclines Mr. Hodgson to agree with Storrow as to the impossibility of the occurrence of separate races of herring in the North Sea, so far as the southern half is concerned.

The Hyomandibula of Fishes.—In an important paper on this subject (*Jour. Anat.* 60, pp. 173-93, January 1926) Prof. F. H. Edgeworth, as an adherent to the theory of Gegenbaur that the hyomandibula in the Teleostomi is homologous with that in the Selachii, reviews the recent theories of Allis, Schmalhausen, and de Beer and, after critical examination, rejects them in favour of the Gegenbaur hypothesis. In support of this view he advances the following facts: (1) In both groups of fishes the hyoid bar is at first a continuous one, its upper end at first not reaching the auditory capsule, though afterwards doing so; (2) the hyomandibular is the segmented-off upper part of this bar; (3) it comes into relationship with the auditory capsule in both groups; (4) the relations of that portion of the hyoid constrictor muscle which forms a levator hyomandibulæ are similar in the Chondrostei and Selachii. The curious condition found in Ceratodus he concludes is almost certainly secondary.

Pelvic and Thigh Muscles in Ornithorhynchus.—Miss Helga S. Pearson (*Jour. Anat.* 60, pp. 152-63, January 1926) has made a detailed study of these muscles in Ornithorhynchus with the view of interpreting their homologies in the light of recent work on the homologies of the muscles of the Vertebrata based on a study of fossil forms, especially the work of Romer on the locomotor apparatus of amphibia, reptiles, and mammals. Romer had not dissected any monotreme himself, but relied on earlier descriptions for the conditions obtaining in this group. Miss Pearson's work, therefore, supplements Romer's in this respect. She rejects the views of the earlier workers, especially Westerling, on the homologies of the muscles in this group, and finds that, so far as the pelvic and thigh muscles are concerned, they can be readily brought into line with Romer's ideas. They are essentially mammalian in their arrangement, but sometimes still suggest a reptilian origin. Miss Pearson has carefully described each muscle and indicated its reptilian homologue in Romer's scheme. The paper is well illustrated by a series of carefully constructed and very clear figures.

Artificial Cells.—Year Book No. 24, issued by the Carnegie Institution, Washington, contains brief progress reports on a number of interesting investigations. Under the director, Dr. D. T. MacDougal, the laboratories for plant physiology at Tucson, Arizona, and Carmel, California, continue the attempt to parallel the phenomena of absorption by the plant cell, by the properties exhibited by artificially constructed cells. One definite success is recorded, in that the artificial cell, if agar, pectin, and gelatin are used in appropriate proportions and method in its construction, shows the same sort of anomalous behaviour, in removing potassium ions selectively from solution containing both sodium and potassium ions, as is shown by the living plant cell. Beverly L. Clarke reports upon this investigation, as also upon some interesting experiments on the condition governing the swelling of agar gels.

Antennæ of Trilobites.—Hitherto the antennæ have been found in only four species of trilobites belonging to the genera Neolenus, Triarthrus, Trinucleus, and Calymene, which range in age from Middle Cambrian to Upper Ordovician. In a large collection of trilobites from the Lower Cambrian of Lancaster County, Pennsylvania, which has been received by the Peabody Museum, Yale University, C. O. Dunbar (*American Journ. Sci.* 9, 1925, p. 303) has discovered the antennæ in one specimen of Olenellus. They appear to have been about half as long as the body. The species of Olenellus is regarded as new, but closely resembles *Olenellus Thompsoni*.

Australian Wind Storms.—A discussion on Australian hurricanes and related storms, with an appendix on hurricanes in the South Pacific, prepared by Mr. Stephen S. Fisher of Chicago and Mr. D. Hodge of the Bureau of Meteorology, Melbourne, has been issued under the direction of Mr. H. A. Hunt, Commonwealth Meteorologist (Bull. No. 16, Bureau of Meteorology, Melbourne). The publication has been undertaken that all recorded data regarding the occurrence of hurricanes in Australia and the surrounding tropical waters might be available for the information of mariners and shipping interests generally. In Australia the Queensland coast is most often affected by hurricanes. In the thirty-four years 1890–1923 they averaged one or two a year, coupled annually with two or three storms of less severity. Four-fifths of the storms occur in the five months December to April, and two-thirds of the storms occur in January, February, and March. Most of the hurricanes which affect Queensland come from the east; many recurve near the coast and pass southward, frequently so far as Brisbane. Western Australia has, on the average, rather more than one hurricane a year. In the fifty-two years 1872–1923, 74 severe tropical cyclones were recorded; some years had as many as three, and one year, 1917, had five.

Of the less severe types of storm, Western Australia has fewer than Queensland. The portion of Western Australia which is most often damaged by hurricanes lies far north of Perth. The hurricanes are most frequent in the hotter months. The Northern Territory has fewer cyclones than Queensland or Western Australia. Attempts have been made to issue long-previous predictions of hurricanes but no satisfactory result has been attained. Maps are given showing the hurricane season in different parts of Australia and the movement of the hurricanes at different seasons of the year.

Measurement of Air-flow.—Methods of air-flow measurement are of importance in many industries and in factories where fans are utilised for ventilation. The Pitot-static tube is the instrument most commonly used for accurate determination of air-flow velocity, but little detailed information is available regarding its characteristics. It consists of an open-ended tube facing the wind, with holes situated in a concentric tube aft of the open end. Both openings are normally connected to the ends of a water-gauge and the pressure difference gives a reading proportional to the square of the air-flow velocity. Experience with the National Physical Laboratory standard instrument has shown that, although accurate under certain conditions, it is defective in many respects. Investigations described by Messrs E. Ower and F. C. Johansen (Aeronautical Research Committee, R. and M. 981, "The Design of Pitot-static Tubes" London: H.M. Stationery Office, 1925. Price 9*d.* net) have now indicated that these defects may be eliminated by the following precautions: The static holes in the concentric tube should be at least six diameters back from the base of the head, and the supporting stem at least fifteen diameters downward from the holes. The calibration will then be practically independent of the shape of head used, and therefore insensitive to relatively large variations in the form of the nose, so that considerable latitude in the manufacture of duplicates will be permissible without entailing special calibration. From both aerodynamic and mechanical considerations a hemispherical nose is most suitable. The instrument is then markedly less sensitive than the standard Pitot-static tube to angular deviations of the wind, an important feature.

River Sounding Experiments.—The determination of submerged contours by the process known as sounding has always been subject to the difficulty of ensuring perfect verticality in the sounding chain, or wire. In most cases, the divergence from the perpendicular has not been of serious moment, but it can readily be understood that, in taking measurements in order to compute the discharge of a river in flood, as close an approximation as possible to the actual depth is of the utmost importance. The matter forms the subject of a monograph prepared by Dr. Phillips of the Egyptian Hydrological Service ("An Experiment to Determine Corrections to Sounding in River Gauging," Government Publications Office, Ministry of Finance, Darawin P.O., Cairo, price P.T. 5). He states that the practice at discharge sites in Egypt has been to sound with a heavy conical lead weight of about 48 kgm. suspended by a piano wire of 1·6 mm. diameter. A stay wire is fixed to the weight and pulled, from some point well forward in the boat, until the part of the suspension wire which can be seen above the water is vertical, and it has been assumed, with a certain amount of latitude, that in this position the sounding measured is a true sounding. Dr. Phillips proceeds to describe the experiments he made with the view of ascertaining the correction necessary to be introduced in order to rectify the deviation of the sounding wire caused by the flow of the current. The problem was attacked by suspending the sounding weight from the side of a launch and dragging it through still water at various speeds and with various lengths of sounding wire. By this means the curvature of the sounding wire for the respective speeds and lengths was experimentally determined. After, detailing his experiments and recording the results, Dr. Phillips concludes that the corrections have been established with sufficient accuracy.

New Uses for Metallic Tantalum.—It is stated in the *Chemiker-Zeitung* that Messrs. Siemens, Halske and Co have succeeded in solving the problem of producing pure metallic tantalum in the form of large blocks and sheets of foil, which will be likely to provide most useful material for the manufacture of scientific apparatus. At ordinary temperatures the metal remains untarnished in air, and it resembles the noble metals in its resistance to the attack of chemical reagents In particular, it is said to be unaffected by all acids except hydrofluoric acid. When first prepared by the same firm in 1903 it was used for making the filaments of incandescent electric lamps, but for this purpose it has been superseded by tungsten, which melts at a higher temperature. It is claimed, however, that it is still superior to all other metals for the manufacture of the electrodes of high-vacuum tubes, and it has also been used extensively for making small surgical and dental instruments. Basins of platinum may now be replaced by basins of tantalum, since the latter metal resists chemical action satisfactorily, and it can also be heated to redness for long periods without deterioration. Moreover, it is claimed that electrodes of tantalum are superior to platinum electrodes in the electrolysis of metallic salts. Thus in the electrolysis of common salt the electrodes are not attacked; in the case of zinc salts the cathode forms no alloy with the zinc, so that no coating with copper or silver is necessary. When used as anodes, the metal usually protects itself from attack with a layer of oxide. By means of the new process the firm has been able to reduce the cost of the metal to about one-twelfth of that of a similar *weight* of platinum.

Separation of the Isotopes of Chlorine.—Further experiments on the separation of the isotopes of chlorine by diffusion and the determination of the atomic weight of the light fraction are described by W. D. Harkins and F A Jenkins in the January number of the *Journal of the American Chemical Society* It will be remembered that previous experiments reported in Nature dealt with the heavier fraction, and that chlorine of atomic weight 35·515, about 0·058 higher than ordinary chlorine, was obtained by diffusion methods. The present paper deals with the results of a series of diffusions of hydrogen chloride through the stems of Scotch clay churchwarden pipes at atmospheric pressure. The aim was to produce chlorine of atomic weight lower than that of ordinary chlorine, and in the final product the atomic weight was found to be 35·418, or 0·039 less than that of ordinary chlorine The extreme separation of chlorine into light and heavy fractions thus represents a change of atomic weight of 0·097 unit, or 1 part in 365. It is pointed out that this is the greatest relative difference of atomic weight obtained by artificial means for any element The atomic weights were obtained by determining in quartz flasks the ratio of the weights of highly purified silver to extremely pure silver chloride, with no transfer of silver or silver chloride from one vessel to another.

The Kansas City Meeting of the American Association.

THE annual meeting of the American Association for the Advancement of Science was held at Kansas City, Missouri, December 28, 1925–January 2, 1926. This gathering was the eighty-second meeting of the Association. With it met twenty-nine scientific societies. The total registered attendance was 1931. The total number of papers read was 985.

The policy of the American Association differs from that of the British Association in encouraging the reading in sectional meetings of large numbers of communications, especially many by younger scientific workers. In another respect, however, the practice of the British Association was followed to advantage at Kansas City, namely, in that there were a number of evening and afternoon lectures specially arranged for the general public, seven in all. All sessions of sections, and the various society meetings, were open to the public Several radio talks were arranged, and popular accounts of a large number of the papers were prepared for wire and mail service to the daily press by a local publicity committee and by Science Service, of Washington.

The address of the retiring president of the American Association, Dr. J. McKeen Cattell, editor of *Science* and the *Scientific Monthly*, was delivered on the evening of the opening day. Dr. Cattell spoke on "Some Psychological Experiments," emphasising the application of methods of psychological measurement to modern industrial and social problems.

The paper selected by the award committee for the annual 1000 dollar prize of the American Association, as an outstanding contribution to science presented at the meeting, was by Prof. Dayton C. Miller, of the Case School of Applied Science, Cleveland, Ohio, and was entitled "The Michelson-Morley Ether-Drift Experiment, its History and Significance." This paper was read on the Tuesday afternoon, as the presidential address of the American Physical Society.

A paper on a related subject was presented on the following day by Prof James Pierpont, of Yale University. Prof. Pierpont's address was delivered under the auspices of the American Mathematical Society, as the third annual Josiah Willard Gibbs lecture. His title was "A History of Man's Effort to Solve the Problem of Space, and the Effect of Relativity on Our Views."

Two symposia were led by Prof. Michael I. Pupin, president of the Association. The first was held by the Engineering Section on the Wednesday evening, with a discussion of the relation of engineering to the fundamental sciences. On Thursday afternoon the Committee of One Hundred on Scientific Research discussed the problem of the encouragement of research workers and of securing co-operation among them. The same question was attacked by Dr. Vernon Kellogg, secretary of the National Research Council, whose address before the Entomological Society of America was entitled "Co-operation or Isolation in Science?"

President F D Farrell, of Kansas State Agricultural College, chose as the topic of the fourth annual Sigma Xi lecture "The Desert Becomes a Garden," telling how the region between the Missouri River and the Rocky Mountains, once marked on the maps as the "Great American Desert," has become one of the most productive agricultural areas in the world. The whole of Wednesday afternoon was devoted to a symposium on prairie ecology, participated in by the botanical and zoological groups.

The newly elected president of the Association is Dr. Liberty Hyde Bailey, formerly dean and director of the New York State Agricultural College at Cornell University, Ithaca, N Y., well known as the writer and editor of many works on botany and on various aspects of horticulture and agriculture, as well as on rural life in general. Dr. Bailey was also chosen president of the Botanical Society of America

The next annual meeting of the Association will be held in Philadelphia, and later annual meetings are planned for Nashville, Tennessee; New York City; Des Moines, Iowa; Cleveland, Ohio; and New Orleans, in order. This series of meetings will complete the first of the twelve-year cycles contemplated in the plan inaugurated at the Chicago meeting in 1920. According to that plan, the Association is to meet in Chicago, Washington, and New York in rotation once each quadrennium, meetings during the interim years being held in other cities, alternating between larger and smaller places, and between locations in the eastern States and in the west and south.

FRANK THONE.

The Standardisation of Insulin.

THE position which insulin holds in clinical medicine in the treatment of diabetes would never have become so firmly established if the manufacture of the product had not been controlled. The appearance on the market of preparations of varying potency, perhaps even inactive, would have led to a great delay in the recognition of the usefulness of this compound, perhaps even to a certain amount of scepticism as to its actuality. To control production adequately, then, meant the discovery of a method by which the activity of different samples could be accurately compared and expressed in terms of some known standard. The latter was, and is still, defined in terms of the blood-sugar reducing power of insulin, after injection subcutaneously into normal rabbits. Thus one rabbit unit is that amount of insulin which will reduce the blood-sugar of a 2 kilo. rabbit, starved for twenty-four hours, to the convulsive level of 0·045 per cent.: a clinical unit is one-third of this amount and is the unit which is now generally used. The problem of putting on the market samples of insulin of known and unvarying potency has been simplified by the issue, to those manufacturing the product, of a solid powder (the hydrochloride of insulin), the activity of which has been determined by the authorities controlling the manufacture: this standard powder is now in use in different countries, so that all samples produced should be of the same activity. But this, of course, depends upon the accuracy of the assay of the sample against the standard.

Methods of estimating the activity of insulin preparations have been developed utilising both the blood-sugar reducing property and also a secondary result of this property, the production of convulsions on doses which reduce the blood-sugar to levels of 0·045 per cent. or lower. Owing to the fact that the occurrence of convulsions in a group of animals is much less regular than a fall in the blood-sugar after a dose of insulin, to obtain consistent results very large numbers of animals must be used, either rabbits or, perhaps more conveniently, mice. But even utilising the first method, complications arise from the fact that different animals react very differently to the same dose of insulin on the same day, and the same animal shows definite variations to the same dose on different days. A method, therefore, which tends to eliminate such variations increases the accuracy of the assay, the "crossover" test described by H. P. Marks (*Brit. Med. Journ.*, 1925, vol. 2, p. 1102) appears to a great extent to fulfil this condition Rabbits of about 2-3 kilo. in weight are used, those which convulse on one unit per kilo. or are abnormally insensitive having been previously eliminated from the stock. The principle of the method is to divide the rabbits into two groups, of which one is given a dose of standard and the other a dose of the sample, and then to repeat the test a few days later, reversing the doses given to the two groups In this way variations affecting the whole of the rabbits, the bulk daily variations in sensitiveness, are eliminated entirely, or almost entirely, since different rabbits may respond somewhat differently to these bulk variations, moreover, by using a large enough number of animals, it is possible to eliminate to a great extent the individual variations, which may be in the direction of either increased or decreased sensitiveness, since these variations may be supposed to cancel out

The details of the actual test are as follows the rabbits, at least six, preferably twelve or even more, are starved for the twenty-four hours preceding the test On the morning of the test, blood is drawn from an ear vein of each rabbit, and then half are given a dose of standard corresponding to 0·5 unit per kilo. subcutaneously, and the other half a dose of the sample, which is assumed to be of about the same value. Blood is drawn from the ear every hour after the injection for five hours, by which time the blood-sugar has usually returned to its initial level. A little more than 1·0 c.c. of blood is drawn at each bleeding, the blood-sugar being estimated by the Shaffer-Hartmann method. The average value for the blood-sugar over the five hours after the injection is found and subtracted from the initial value the result, expressed as a percentage, is known as the "percentage reduction" of the blood-sugar After at least three days the test is repeated on the same group of rabbits, starved for the preceding twenty-four hours, but the rabbits which previously had a dose of the standard are now given a dose of the sample, and vice versa. The sum of all the percentage reductions on the sample is now compared with the sum of those obtained on the standard, the result being expressed as a percentage of the latter. When the sample has a strength of about 100 per cent compared with the standard, the standard error is about 2·5, trial of the method with known doses of standard tested against 100 per cent. standard showed that the effect produced tended to be closer to the 100 per cent than the actual dose given. thus a dose of standard 110 per cent. against standard 100 per cent. gave a result of 106 per cent, whilst a dose of 80 per cent appeared to be 83 per cent.; moreover, the standard errors with these two doses were 3·7 and 6·3 respectively. From the figures given it is possible to calculate the actual strength of a solution of insulin with a fair degree of accuracy, to make the appropriate change in its strength to bring it to 100 per cent and, on retesting, to feel fairly confident that the result obtained will agree, within about 5 per cent., with the result expected.

Do insulin solutions of somewhat varying potency, assayed in the laboratory on *normal* rabbits, show parallel variations in potency when used clinically on *diabetic* patients? According to G A. Harrison and R D. Lawrence, in a continuation of the same paper (p 1104), this is now the case Although in the early days of insulin testing variations in the activity of different samples of insulin could be detected clinically, and clinical results did not agree always with those obtained in the laboratory, during last year the laboratory tests agreed very closely with the clinical tests, so that the authors conclude that the method of assay above described gives results which are perfectly satisfactory for determining the potency of solutions to be used clinically. In the performance of the clinical tests strict adherence to diet and daily routine is essential the two samples of insulin are given on successive days and the resultant falls in the blood-sugar plotted as superimposed graphs. if the curves show a reasonable coincidence, the samples are considered to be of the same strength; if one appears stronger than the other, the test is repeated later, using doses which are more nearly comparable. It should be emphasised that small differences in the strength of different batches will not be detected clinically unless the patient's whole daily routine is kept absolutely constant. The authors consider that variations of 10 per cent. from the standard will not be inconvenient clinically: as has been seen above, the method of assay worked out by Marks is capable of determining even smaller differences.

The Lines of the Solar Spectrum.

AN important paper by K. Burns and W F. Meggers, dealing with the wave-lengths of lines in the solar spectrum, appears in Vol 6, No. 7, of *Publications of the Allegheny Observatory*. In order to investigate a number of problems connected therewith, the Allegheny Observatory co-operated with the Bureau of Standards, Washington, the observations being made at the former institution and the measurements jointly. The problems dealt with in the present paper are the errors in Rowland's measurements of solar wave-lengths over a limited range of spectrum, and a preliminary study of the relative wave-lengths of lines in the solar and terrestrial spectra. An image of the sun was formed in a Fabry-Perot interferometer by a lens of 40 cm. focal length. The issuing light was focussed by a quartz-fluorite achromatic lens on the slit of a spectrograph containing a Michelson grating having 500 lines per mm. and giving a dispersion of 3 65 Å U. per mm. in the first order. The resulting spectrum therefore appeared as a number of line images of the slit, each crossed by segments of the interference ring system, the centre of which coincided with the centre of the spectrum line. Special attention was given to a disturbing interference effect which disappeared when the slit width was properly adjusted, and the paper contains a useful discussion of the interference phenomena associated with a continuous spectrum

The wave-lengths were measured by comparison with those of standard lines of neon. Light from a neon lamp was reflected through the same apparatus by means of a half-silvered diaphragm placed before the interferometer, and the neon lines, crossed by rings, were photographed in an auxiliary camera of shorter focus. The thickness of the interferometer (ranging, in separate experiments, from 3 75 mm to 10 mm.) was computed from the neon lines, and the solar wave-lengths were thereby calculated. A table gives the wave-lengths of 201 lines in the region λ4754 – λ4073 and the corrections to be applied to

Rowland's values at frequent intervals throughout this region.

In order to compare solar and terrestrial wave-lengths a vacuum iron arc was used, the comparison being made either by simultaneous exposures to sun and arc or by successive exposures and independent comparison with neon. A systematic shift of the solar lines to the red was revealed, which increased with both intensity and wave-length, within the region above quoted. It is stated that the dependence on wave-length might be merely an indirect effect of the dependence on intensity, arising from the difficulty in comparing intensities in different regions of the spectrum. Owing to the need for more extended investigation, no attempt is made to form a judgment concerning the nature of the red shift, but the shift itself and its variation with intensity are regarded as real, and as making it impossible to say at present whether or not the Einstein displacement exists in the solar spectrum.

University and Educational Intelligence.

ABERDEEN.—The University Court has appointed Dr. A. W. Borthwick, senior research officer to the Forestry Commission, to the chair of forestry; and Dr. J. Cruickshank, reader in bacteriology in the university, to the chair of bacteriology. Both are first appointments to recently founded chairs.

Sir David Prain has been appointed to deliver a university lecture in the science faculty.

CAMBRIDGE.—Mr S. Lees, fellow of St. John's College, has been reappointed as Hopkinson lecturer in thermodynamics. Mr. F. Debenham, fellow and tutor of Gonville and Caius College, has been appointed Director of the newly formed Polar Research Institute.

The Pinsent-Darwin Studentship has been allotted to Dr. R. D. Gillespie, of the Cassel Hospital for Functional Nervous Disorders, for the period of three years.

A Scientific Research Fellowship at Girton College of the value of 300*l.* a year is offered for research in mathematical, physical, and natural sciences. Women who are graduates or have taken honours in a final degree examination of any university, and members of the Girton College Roll, are eligible. The appointment will be for three years in the first instance. Applications must reach the Secretary of the College on or before April 12. The proposed course of research, and a dissertation or published work, and other evidence of fitness to undertake the research, are required.

LONDON.—A course of three public lectures on "The Constitution and Evolution of the Stars" will be given by Prof. A. S. Eddington at King's College, at 5.30, on February 22, 24 and March 1. A similar course, on "Some Principles of Therapeutics," will be given at St. Thomas's Hospital Medical School at 5.30, on February 22, 23, and 24, by Prof. D. Murray Lyon. No tickets are required in either case.

Three further courses of free public lectures are announced, namely: "The Morphology of the Vascular Cryptogams in the light of Pre-carboniferous Plants," by Prof. W. H. Lang, at University College, on March 1, 3 and 5, at 5.30; "Active and Passive Immunity," by Dr. R. A. O'Brien, at University College Hospital Medical School, on March 1, 5, 8 and 12, at 5, and "Atomistic Physics," by Prof. A. Sommerfeld, at the Imperial College of Science, on March 3, 9 and 10, at 5.30.

BRITISH Dyestuffs Corporation is again granting facilities to a limited number of university students taking honours schools in chemistry, to enable them to gain an insight into chemical works practice. The students must be of British birth, have no direct connexion with the dyestuffs industry or industries competing with the Corporation, and they must be recommended by their professor of chemistry. Application forms should be returned to the Corporation at 70 Spring Gardens, Manchester, marked "Vacation Course," not later than May 1. If sufficient applications are received, courses are proposed for the periods July 1-28 and September 1-30 only.

THE Ramsay Memorial Fellowship Trustees in their report for 1924–25 give particulars of the eighteen fellowships (including five temporarily vacant) which they are administering. These fellowships are for research in chemistry and are, ordinarily, worth 300*l.* a year for two years. Those awarded in 1924–25 were held at University College, London (5), King's College, London, the Imperial College of Science and Technology, London, Oxford (2), Cambridge (2), Bristol, Manchester, Sheffield, and the Davy-Faraday Laboratories of the Royal Institution, London. Eleven of them were held by fellows from other countries: a Canadian at Cambridge under the direction of Sir Ernest Rutherford, a Dane under Prof. M'Bain at Bristol, a Dutchman under Prof. Robert Robinson at Manchester, a Frenchman under Sir William Bragg at the Royal Institution, a Greek under Prof. E C Williams in the Ramsay Laboratory of Chemical Engineering at University College, London, an Italian at Cambridge under Prof. Lowry, a Japanese and a Spaniard under Prof. F. G Donnan at University College, London, a Norwegian at Sheffield in the Department of Metallurgy, a Swede at King's College, London, under Prof. Richardson, and a Swiss at the Royal School of Mines, Imperial College, under Prof. H. C. H. Carpenter.

THE Commonwealth Fund Fellowships were established a year ago by the Commonwealth Fund of New York, a philanthropic foundation existing since 1918 and supported by gifts from Mrs. Stephen V. Harkness. They are tenable by British graduate students at American universities and are worth about 600*l.* a year for two or, in exceptional cases, three years. A report of the working of the scheme in its first year, issued last November and recently received, shows that every university and university college in Great Britain and Ireland, with one exception, sent in candidates, and that on the final list Cambridge, Durham, Edinburgh, Leeds, London, Manchester, Oxford, Belfast, St. Andrews, and Wales were represented. The chosen subjects of study of the twenty successful candidates are: Agriculture, architecture, botany, chemistry (3), classics, economics (2), English (2), geology (2), history, law, mathematics, medicine (2), and physics (2). The fellowships will be held in the first instance at the following universities Harvard (3), Yale (2), University of California (2), Cornell (2), University of Wisconsin (2), Johns Hopkins (2), University of Chicago (2), Columbia (2), University of Illinois, Princeton, University of Minnesota One of the conditions of tenure is that fellows are required to travel for three months in the United States at the end of the first year. Each fellow is asked to submit by the middle of the academic year a plan for travel in connexion with his work, for example, to visit libraries, laboratories, or universities. Advice regarding the plan is offered by the New York office of the Fund, and letters of introduction when possible, and sufficient allowance is made for comfortable travel.

February 25, 1869.	Prof. Arthur W. Crossley, F.R.S.
February 26, 1864.	Mr. John Evershed, F.R.S.

The DUKE OF BEDFORD, who was born in London, graduated at Balliol College. His Grace is a trustee of the British Museum and president of the Zoological Society of London.

Prof. ARRHENIUS was born at Wijk, near Upsala. He is the originator of the theory of electrolytic dissociation, and was Nobel laureate in 1903. In the previous year he was awarded the Davy medal of the Royal Society for his application of the theory of dissociation to the explanation of chemical phenomena. In 1914 the Chemical Society allotted him its Faraday medal, and Prof. Arrhenius received it in person. On that occasion Sir William Crookes said, "The world is deeply in need of researchers both of the type of those whose genius is characterised by that fertility of resource in experimental investigation exhibited by Faraday and the type of Arrhenius. Both are revolutionaries and founders of new kingdoms. The world's debt to them is incalculable."

Dr. MATTHEW, palæontologist, was born at St. John, New Brunswick. He is curator of fossil vertebrates in the American Museum of Natural History, New York.

Sir SVEN ANDERS HEDIN, explorer and geographer, was born at Stockholm and educated there and in various foreign cities In 1902 he was ennobled by the King of Sweden. He is Hon. D.Sc. (Oxon., Camb.). The Founder's medal of the Royal Geographical Society was awarded him in 1902. Sir Sven published "My Life as an Explorer" in 1925.

Dr. M. J. M. HILL, formerly professor of mathematics in the University of London, was born at Berhampore, Bengal. Educated at Blackheath, University College, London, and Peterhouse, Cambridge, he was 4th wrangler and Smith's prizeman (1879).

Viscount CAVE was born in London. Educated at Merchant Taylors' School, he graduated at St. John's College, Cambridge. Lord Cave is chairman of the Grand Council of the British Empire Cancer Campaign.

Prof. CROSSLEY is a Lancashire man. He went to Mill Hill School, and afterwards he graduated at the University of Manchester. He is also Ph.D. (Wurzburg) Formerly Daniell professor of chemistry in the University of London (King's College), he is now director of the Cotton Industry Research Association, Didsbury. Prof. Crossley is an Officer of the Legion of Honour.

Mr. EVERSHED, until lately director of the Kodaikanal and Madras Observatories, is distinguished for his work in astrophysics. In 1918 he was awarded the gold medal of the Royal Astronomical Society for his investigations of the radial motion in sunspots, and more recently he has detected the shift of the lines of the solar spectrum required by the theory of relativity.

Societies and Academies.

LONDON.

Royal Society, February 11.—H. G. Thornton and N. **Gangulee**: The life-cycle of the nodule organism *Bacillus Radicicola* (Beij) in soil, and its relation to the infection of the host plant. A regular cycle of changes was found, unbanded rods, cocci, and banded rods successively predominating in the soil. Increase in the percentage of cocci was associated with increased bacterial numbers and with the appearance of motile forms. When soil and sand is inoculated with a suspension of the bacteria, the latter commence, after a lag period, to spread radially at an approximate rate of 1 inch in 24 hours. The lag is apparently related to the time taken for cocci to predominate in the soil, and is decreased by using milk and 0·1 per cent. of calcium phosphate as the inoculating fluid. The bacteria multiply rapidly in the soil into which they have recently spread. Lucerne plants grown from seed inoculated with a suspension of bacteria in milk + 0·1 per cent. calcium phosphate showed a considerable increase in nodule numbers and in yield compared with plants from seed inoculated with a suspension in milk alone.—C. E. **Walker**: The meiotic phase in certain mammals. The daughter chromosomes of the last somatic division before the first meiotic split longitudinally. The semivalent half-chromosomes lengthen out, until the whole nucleus is filled with fine semivalent threads. This is the end of the telophase. These semivalent threads join together again in pairs to form univalent filaments, which join laterally in pairs to form bivalent loops. The filaments, after forming these loops, separate except at their ends. These are the meiotic bivalent chromosomes. At the first meiotic division, the pairs of whole somatic chromosomes, joined by their ends, separate and are distributed, half to each daughter cell. The longitudinal split in the daughter chromosomes of the somatic division which reappears in the telophase of the first meiotic division, is not consummated until the second meiotic division. The term "exeilesis" is suggested for the process by which each of the daughter chromosomes becomes converted into two semivalent threads.—J. **Needham** and Dorothy **Needham**: Further micro-injection studies on the oxidation-reduction potential of the cell interior. The results of the micro-injection of pH and rH indicators into living cells have been investigated. Oxidation-reduction potential indicators exhibit no anomalies when injected into *Amœba proteus*. It appears, therefore, that all the dyes on the scale may be used with biological material. The amœba is capable of oxidising the leucoform of indicators of lower oxidation-reduction potential, and the latter is probably independent of the percentage of oxygen in the external atmosphere. *Nyctotherus cordiformis* (an anaerobic protozoon) possesses an internal pH of 7·1 and an internal rH of 19·0-20·0 under aerobic conditions, while under anaerobic conditions, the latter changes to 9·5-10·5.—J. W. H. **Harrison** and F. C. **Garrett**: The induction of melanism in the Lepidoptera and its subsequent inheritance. Both in the British Isles and on the Continent in large manufacturing and urban areas, melanic forms have arisen. The conditions point immediately to the smoke in the atmosphere of large towns as responsible for the melanism and, moreover, indicate that it influences insects in the larval state by means of their food-plants. Thus it should be possible to induce melanism by (1) feeding up non-melanic strains of Lepidoptera in melanic districts, and (2) feeding them in non-melanic areas on food-plants artificially charged with impurities known to exist in or on the foliage of plants found in manufacturing centres. Both methods were employed on *Selenia bilunaria*, *Tephrosia crepuscularia*, and *T. bistortata*. Melanic examples appeared in all the experimental broods, and in numbers diverging widely from Mendelian expectation. The melanism so induced in *Selenia bilunaria* and *Tephrosia bistortata* behaved as a Mendelian recessive, while in *T. crepuscularia* it acts as a dominant.—J. **Gray**: The mechanism of ciliary movement.—(v.) The effect of ions on the duration of beat.—N. H. W. **Maclaren**: The early development of Cavia: Note on associated remains of previous placentation.

Linnean Society, January 21.—H. B. **Fantham** and Annie **Porter**: On two protozoan parasites found in the latex of *Ficus edulis* and *Euphorbia striata*. Two species of herpetemonads were found respectively in the latex of *Euphorbia striata* and *Ficus edulis* in Johannesburg, South Africa; the former is probably a strain of *Herpetomonas* (*Leptomonas*) *davidi*, and the latter is regarded as a new species. The plants parasitised do not show any marked pathological symptoms, the infection being localised. The number of infected plants was very small in each case. The possible source of the herpetemonads is of interest. They are best known as parasites of the alimentary tract of insects, both blood-sucking and non-blood-sucking. Marks of punctures, very probably made by the proboscides of plant-feeding Hemiptera, were seen on the Euphorbia, while green flies, Lucilia sp., were found on the fig-leaves, which may have inoculated the flagellates into the latex of the plants. They occur in man and dogs under the name of *Leishmania kala-azar*, and skin-sores are caused by them. It is interesting to find the latex of certain plants forming a natural reserve of herpetemonads.—H. H. **Thomas**: Discussion: The relation between the Caytoniales and modern flowering plants. The recently described Caytoniales are of some interest because they were Angiosperms without flowers, their reproductive structures being megasporophylls bearing carpels and microsporophylls bearing anthers. A single carpel and a single anther of this fossil type can be compared somewhat closely with the corresponding structures in the modern flower. It is unlikely that the Caytoniales represent the direct ancestors of the flowering plants, but they may be derived from the same stock which gave rise to that group. Assuming some relationship, the structure of Caytonia points to the carpels of the primitive Angiosperms having double rows of ovules produced in a dorsal median position near the vascular strands, rather than to the occurrence of marginal ovules produced on the sides farthest away from the vascular strands. Caytonia and Gristhorpia were undoubtedly wind-pollinated, and contained many ovules in each carpel. They can therefore be cited in opposition to the views (Robertson) that the primitive Angiosperms were insect-pollinated. The seeds of the Caytoniales are small in size and do not agree with the view that the primitive Angiosperm seeds were large like those of Cycas. The comparison of the microsporophylls (*Antholitus Arberi*) with the modern stamens may indicate that the primitive anther had four equal pollen-sacs arranged longitudinally, and was inserted by its base on the filament. A group of plants resembling both the Caytoniales and the Bennettitales, and also derived from the Pteridosperms, is suggested as the origin of many flowering plants. Recent discoveries tend to show that the Angiosperms originated at a much earlier period than was formerly supposed, and that at least one group of early Angiosperms achieved a very wide distribution in early Mesozoic times.

PARIS.

Academy of Sciences, January 11.—Pierre **Weiss**: Paramagnetism independent of the temperature. Solutions of luteocobaltic chloride and of potassium bichromate possess a magnetisation coefficient independent of the temperature. This fact is of importance in the theories of paramagnetism. A discussion of the possible hypotheses leads to the conclusion that constant paramagnetism should be an intra-atomic phenomenon.—Ph. Le **Corbeiller**: The substitutions of the complex modular group.—Ladislas **Nikliborc**: Hyperharmonic functions.—J. Kampé de **Fériet**: The uniformisation of a class of functions defined by integral series with meromorph coefficients.—Constant **Lurquin**: Binary covariation.—— **Kivelioviteh**: The conditions of a binary shock in the problem of three bodies.—Emile **Belot**: Remarks on the dense internal nucleus of the sun and on the movement of sunspots in latitude.—— **Pauthenier**. The photographic measurement of the electrostriction in the case of carbon tetrachloride. The experiments described are in good agreement with theory for the case of carbon tetrachloride.—H. **Pélabon**: Detection and the stability of certain detectors. Any imperfect contact metal-dielectric-metal may be used as a detector of wireless waves. If the dielectric interposed is gaseous the detector obtained is unusable on account of its extreme instability due to temperature changes. Powdered, badly-conducting solids form stable detectors.—— **Andrieux**: The electrolysis at a high temperature of oxides dissolved in boric acid or in borates. Details of a method by which sodium can be obtained by the electrolysis of borax.—— **Baykoff**: The theory of hardening of hydraulic cements. The author considers that three stages can be traced in the hardening of cement. The first stage is one of solution during which the liquid becomes saturated with the various soluble constituents. In the second stage all the products of the chemical reaction enter into the colloidal state. This corresponds to the commencement of the setting. In the final stage the gels are transformed into crystalline aggregates and this is the period of hardening.—A. **Kling** and A. **Lassieur**: The stability of solutions of carbonic acid. In a previous communication the authors have shown that water, purified as completely as possible, possesses an acid reaction, corresponding to $pH = 5{\cdot}8$. One plausible explanation of this would be that it is due to retained carbon dioxide. Direct experiment proved that a solution of carbon dioxide in highly purified water lost the whole of its carbon dioxide on exposure to air and gave the same acidity (5·8) as water purified without access to carbon dioxide.—Georges **Delbart**: Study of the fragility of cold drawn steel.—T. **Karantassis**: Researches on stannous chloro-iodide, bromo-iodide, and chloro-bromide. Data are given in support of the existence of the definite compounds $SnICl$, $SnIBr$, and $SnClBr$.—J. **Bougault**: An example of ether-oxide of a hydrated ketone.—M. **Faillebin**. The hydrogenation of ketones in the presence of pure and impure platinum black. It has been shown in earlier communications that the reduction products of ketones and aldehydes by hydrogen in the presence of platinum black are affected by the purity of the platinum. In the present paper an attempt is made to study the mechanism of the phenomenon. A platinum-iron catalyst was treated with a mixture of acetic acid and acetylacetone to remove the iron. The catalyst thus obtained functions as pure platinum black in the reduction of ethyl acetoacetate.—Raymond **Delaby**: The catalytic oxidation of vinylalkylcarbinols into vinylalkylketones in the presence of palladium black The oxidation of unsaturated secondary alcohols can only be carried out in a gaseous system at low pressures, but the yields are not good.—André Cornillot: The bis-phthalide carboxylic esters.—P. **Gaubert**: Detection (in wireless telephony) and the facies of crystals of galena and pyrites.—Conrad **Kilian**: The proportion in which the Silurian period is represented by its formation of the Tessilian enclosure, and on the presence of the Ordovician in the Sahara.—G. **Georgalas** and N. **Liatsikas**. The spectrum analysis of the flames from the Santorin volcano (eruption of 1925). From the lines recorded in the spectrograph, the gaseous mixture issuing from the central dome of the volcano contained hydrogen, vapour of sodium chloride, oxygen, nitrogen, and probably ferric chloride.—F. X. **Skupieński**: The evolutive cycle in *Didymium difforme*.—A. **Hée**: The influence of temperature on the intensity of respiration of submerged plants The plants studied were *Elodea canadensis*, *Myriophyllum spicatum*, and Cladophora, and the temperatures varied between 10° C and 39°·5 C. The respiration increased with rise of temperature and there was no optimum temperature.—P. P. **Stanescu**: The quantitative variations of the carbohydrates in the leaves of green plants in the course of a day.—M. **Bridel** and C. **Béguin**: The application of the biochemical method of research to the glucosides undergoing hydrolysis by rhamnodiastase to the study of the fresh roots of *Polygonum cuspidatum*. The production of a new glucoside, polydatoside. The results of the action of rhamnodiastase on the root extract indicated the presence of a new glucoside. Details of the mode of extraction and purification of this substance are given, together with its physical and chemical properties.—L. **Mercier**: The orthogenesis of the longitudinal vibrator muscles of flight in the Diptera.—Jean **Piveteau**: The importance of structural characters in the interpretation of certain fossils classed with the reptiles.—Maurice **Aubertot**: The contractility of the excretory apparatus in the larvæ of *Rhabditis pellio*.—L. M. **Bétancès**: The genesis of the hæmatopoietic organs and of the blood cells in the invertebrates.—A. **Policard**: The movements of sarcomatous cells cultivated *in vitro*. The most marked characteristic of the sarcomatous cells is incessant and rapid amœboid movement.—**Raymond-Hamet**: The action of yohimbine and the active alkaloids of ergot on the sympathetic vasomotor innervation of the kidney.—J. **Risler** and **Foveau de Courmelles**: The physiological action of the ultra-violet rays transmitted by the thin glass in ordinary use. It is generally held that ultra-violet rays emitted by a source of light in the interior of a glass apparatus are not harmful. Four cases of accident resulting from the use of apparatus constructed of light glass are described which show that injurious effects on the skin can be produced by the absorption of rays in the region between $\lambda = 2960$ Å.U. and $\lambda = 3120$ Å.U.—Daniel **Berthelot**: Remarks on the preceding communication. Additional data confirming the results.—R **Fosse**: The formation, by heating plant juices, of urea and of a substance giving the same hydrazine colour reaction as formol. The simultaneous formation, by heating plant juices, of urea and of a substance giving the colour reaction of formol, results from the hydrolysis of a ureide.—G. **Delamare** and Saïd **Djémil**: Abnormal forms of *Plasmodium vivax*.—A. **Paillot**: A new disease of the nucleus or *grasserie* of the larvæ of *Pieris brassicæ* and a new group of micro-organisms.—Mme. **Phisalix**: The natural immunity of the eel against the virus of hydrophobia and the rabicidal action of its serum. The eel is naturally refractory to hydrophobia and its serum destroys the virus of hydrophobia *in vitro*. The serum can also be used to protect animals against hydrophobia.—B. **Issatchenko**: Nitrification in the sea.—X. **Debedat**: Ulcerated Röntgen epitheliomas cured by high frequency treatment (diathermo-coagulation). After giving details of his own cure by this treatment, the author concludes that radiologists need not die of cancer brought on by their work.

Official Publications Received.

Diary of Societies.

SATURDAY, FEBRUARY 20.

BRITISH PSYCHOLOGICAL SOCIETY (Industrial Section) (at National Institute of Industrial Psychology, 329 High Holborn), at 11.30.—Prof. Pear: What is meant by Skill in Industry.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. G. Macdonald: Roman Britain (1).

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.), at 3.—G. Avenell: A Glance at Richard Jefferies (Lecture).

PHYSIOLOGICAL SOCIETY (at King's College).

MONDAY, FEBRUARY 22.

ROYAL IRISH ACADEMY (Dublin), at 4.15.

ROYAL SOCIETY, EDINBURGH, at 4.30.—Rev. T. C. Gordon: The Finding of the Galilee Skull.—Prof. A. Robinson: A Scientific Description of a Neanderthal Skull found in Galilee, from a Cast.

INSTITUTE OF ACTUARIES, at 5.—C. R. V. Coutts: On the Distribution of Life Office Profits.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Fossil Remains of Ape and Man (1): The Taungs Anthropoid: its Zoological and Geological Position.

FARADAY SOCIETY (at Chemical Society), at 5.30.—Prof. A. J. Allmand and R. H. D. Barklie: The Influence of Alternating Currents on the Electrolytic Corrosion of Iron.—A. N. Campbell: The Direct Oxidation of Manganous Ion to Permanganate.—H. J. Poole: The Elasticity of Jellies of Cellulose Acetate in Relation to their Physical Structure and Chemical Equilibria.—F. G. Tryhorn and W. F. Wyatt: Adsorption II. The Adsorption by a Coconut Charcoal of Saturated Vapours of some Pure Liquids. Adsorption III. Stages in the Adsorption by a Coconut Charcoal from the Saturated Vapour over Liquid Mixtures of Alcohol and Benzene and of Acetone and Benzene.—L. R. McHaffie: A Device for Circulating Fluids under High Pressure

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES (at Bedford College for Women), at 5.30.—Prof. J. Johnstone: The Organism and its Environment (Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—A. F. Harmer and others: Discussion on Some Changing Characteristics in the Application of Electricity to Public Supply.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—J. L. Thompson and H. Walmsley: Notes on the Testing of Static Transformers.

INSTITUTION OF STRUCTURAL ENGINEERS (Midland Counties Branch) (at Birmingham), at 7.30.—H. F. Lea: Arterial Road Construction.

ROYAL SOCIETY OF ARTS, at 8.—Dr. G. W. C. Kaye: The Production and Measurement of High Vacua (Cantor Lectures) (2).

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—Sir Frank Colyer: Abnormal Teeth from the Region of the Premaxilla.

RAILWAY CLUB (at 65 Belgrave Road), at 8.15.—B. M. Bailey: Development of the Railway Carriage.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.

TUESDAY, FEBRUARY 23.

ROYAL DUBLIN SOCIETY (at Balls Bridge, Dublin), at 4.15.—Prof. W. E. Adeney and Miss B. B. Dawson: The Estimation of Organic Matter in Water by means of Potassium Bichromate and Sulphuric Acid.—T. G. Mason and C. J. Lewin: On the Rate of Carbohydrate Transport in the Greater Yam, *Dioscorea alata*, Linn.—Prof. J. Reilly: The Production of Lavender Oil from Irish Grown Plants.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. J. Barcroft: The Egg (2): The Shell.

LINNEAN SOCIETY, at 5.30.

ROYAL SOCIETY OF MEDICINE (Medicine, Electro-Therapeutics, Surgery, and Laryngology Sections), at 5.30.—Dr. L. S. T. Burrell, Dr. S. Melville, J. E. H. Roberts, S. Hastings, Dr. W. Gordon, H. M. Woodman, Dr. R. Knox, Dr. D. Forrest, Sir Charlton Briscoe, and others: Discussion on The Diagnosis and Treatment of Intra-thoracic New Growths.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES (at Bedford College for Women), at 5.30.—Prof. L. J. Russell: The Philosophical Problems within Science (Lecture).

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. H. H. Scott: Report on the Deaths occurring in the Society's Gardens during the Year 1925.—W. E. Le Gros Clark and the late Dr. C. F. Sonntag: A Monograph of *Orycteropus afer*. III. The Skull, Skeleton of the Trunk and Limbs, and General Summary.—Dr. Marie V. Lebour: The Young of *Stylocheiron suhmii* G. O. Sars and *Stylocheiron abbreviatum* G. O. Sars (Crustacea), from Mediterranean Plankton collected by Mr. F. S. Russell in the Neighbourhood of Alexandria, Egypt.—Oldfield Thomas: On Mammals from Ovamboland and the Cunene River, obtained during Capt. Shortridge's Third Percy Sladen and Kaffrarian Museum Expedition into South-West Africa.—Helen M. England: Development of Gonophores of the Stylasteridæ.

INSTITUTION OF CIVIL ENGINEERS, at 6.—V. Bayley: The Khyber Railway.—Col. G. R. Hearn: The Survey and Construction of the Khyber Railway.

INSTITUTE OF MARINE ENGINEERS, at 6.30.—F. S. Clifford: The Principles and Practice of Automatic Steering.

ROYAL PHOTOGRAPHIC SOCIETY, at 7.—A. Keighley: Palestine (Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—H. Parodi: The Electrification of the Paris-Orleans Railway.

SOCIETY OF CHEMICAL INDUSTRY (Birmingham and Midland Section) (at Birmingham University), at 7.15.—A. A. Perks: The Heat Reactions occurring during the Vulcanisation of Rubber.

INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 7.30.

ROYAL ANTHROPOLOGICAL INSTITUTE (Indian Section), at 8.15.—R. E. Enthoven: Ethnographic Research in India.

WEDNESDAY, FEBRUARY 24.

INSTITUTE OF HYGIENE, at 3.30.—Dr. L. R. Lempriere: Diet in Schools.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Fossil Remains of Ape and Man (3): Fossil Anthropoids of Europe and of Asia.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. G. L. Elles: The Geological Structure of Ben Lawers and Meall Corranaich (Perthshire).

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (at the Science Museum, South Kensington), at 5.30.—G. F. Tyas: Matthew Murray—A Centenary Appreciation.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES (at University of London Club), at 5.30.—Hon. Bertrand Russell: The Structure of the World (Lecture).

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (at Neville Hall, Newcastle-upon-Tyne), at 7.

SOCIETY OF CHEMICAL INDUSTRY (Nottingham Section) (at University College, Nottingham), at 7.30.—S. R. Trotman and Dr. E. R. Trotman: Further Experiments on the Chlorination of Wool.—Dr. E. R. Trotman: The Determination of Dissolved Oxygen in Effluents.

ROYAL MICROSCOPICAL SOCIETY (Industrial Applications Section), at 7.30.—Kodak, Ltd.: Practical Demonstration of the Eastman Colorimeter.—C. A. Klein: The Application of the Microscope to the Examination of Pigments and Paints.

ROYAL SOCIETY OF ARTS, at 8.—Dr. Mary Fishenden: Domestic Heating.

BRITISH PSYCHOLOGICAL SOCIETY (Medical Section) (at Royal Society of Medicine), at 8.30.—Dr. J. T. MacCurdy: A Hypothetical Mental Constitution of Compulsive Thinkers.

MEDICAL SOCIETY OF LONDON, at 9.—Dr. F. Buzzard: The Principles of Treatment in relation to Diseases of the Nervous System (Lettsomian Lectures) (2).

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section—Newcastle) (at Armstrong College).—Prof. C. J. Hawkes: The New Engineering Laboratories at Armstrong College.

THURSDAY, FEBRUARY 25.

ROYAL SOCIETY, at 4.30.—C. R. Baldwin and Prof. G. B. Jeffery: (*a*) The Relativity Theory of Plane Waves; (*b*) Electronic Orbits on the Relativity Theory.—Margaret Stimson and Prof. G. B. Jeffery: The Motion of Two Spheres in a Viscous Fluid.—A. L. McAulay and F. P. Bowden: Evidence for a Film Theory of Hydrogen Overpotential from Surface Tension Measurements.—*To be read in title only.*—J. H. Wolfenden: Critical Potentials of Hydrogen in the Presence of Catalytic Nickel and Copper.—J. P. McHutchison: Adsorption Experiments with Radium D and Radium E.—J. S. Dunn: (1) High Temperature Oxidation of Metals. (2) The Low Temperature Oxidation of Copper.—Prof. J. Heyrovsky: A Note on The Significance of the Electrode Potential.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Dr. C. D. Ellis: The Atom of Light and the Atom of Electricity (1).

INSTITUTION OF MINING AND METALLURGY (at Geological Society of London), at 5.30.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES (at Royal Anthropological Institute), at 5.30.—H. J. Laski: Politics in Literature. H. G. Wells (Lecture).

ROYAL AERONAUTICAL SOCIETY, at 6.30.—A. J. Cobham: Long Distance Aeroplane Flights.

BRITISH ASTRONOMICAL ASSOCIATION (West of Scotland Section) (at Royal Technical College, Glasgow), at 7.30.—J. J. Ross: The Moon's Motions and Ocean Tides.

OPTICAL SOCIETY (at Imperial College of Science), at 7.30.—C. Aves: Notes on the Significance and Detection of Low Errors of Refraction.—W. H. A. Fincham: Vertex Power and its Measurement.

INSTITUTION OF ELECTRICAL ENGINEERS (Irish Centre (Dublin)) (at Trinity College, Dublin), at 7.45.—Prof. S. P. Smith: An All-Electric House.

INSTITUTE OF CHEMISTRY STUDENTS' ASSOCIATION (London), at 8.—F. H. Carr: The Transference of Chemical Processes to the Large Scale.

FRIDAY, FEBRUARY 26.

ROYAL SANITARY INSTITUTE (in Municipal Buildings, Middlesbrough), at 4.—Dr. Grace Dundas, Dr. C. V. Dingle, and others: Discussions on the Malthriving Infant, the Present Type of Smallpox, Organic Salvage, and Housing and Main Drainage.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section) (at Paddington Green Children's Hospital, W.2), at 4.30.—Clinical Meeting.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—J. H. Calthrop: The Effects of Torsion upon the Thermal and Electrical Conductivities of Aluminium, with special reference to Single Crystals.—T. H. Harrison: A Study of the Concurrent Variations in the Thermionic and Photo-Electric Emission from Platinum and Tungsten with the State of the Surfaces of these Metals.—C. R. Darling and E. Edser: Demonstrations illustrating Surface Tension and Capillary Phenomena.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Fossil Remains of Ape and Man (4): The Kivu Gorilla and its Bearing on the Problems of Human Evolution.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES (at Royal Anthropological Institute), at 5.30.—Prof. T. H. Pear: The Gestalt Theory (Lecture).

SOCIETY OF CHEMICAL INDUSTRY (Glasgow Section) (jointly with Institute of Chemistry) (at 39 Elmbank Crescent, Glasgow), at 7.—Prof. R. A. Berry: Soil Nitrogen.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (at Swansea Technical College), at 7.30.—E. A. Tyler: Some Notes on Pure Chemicals: An Inquiry into the Purity of Available Supplies.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Newcastle-upon-Tyne), at 7.30.—J. Richardson: Hydro-Mechanical Gearing.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—J. F. Petree: Seven Thousand Years of Shipping.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. C. Hagberg Wright: Nicolas de Peiresc and his Circle: The Story of a 17th Century Patron of Learning.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

INSTITUTION OF MECHANICAL ENGINEERS (Sheffield Branch).—Informal Discussion.

SATURDAY, FEBRUARY 27.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (at Neville Hall, Newcastle-upon-Tyne), at 3.—F. J. Johnston: The Use of Breathing Apparatus in Mines.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. G. Macdonald: Roman Britain (2).

PUBLIC LECTURES.

SATURDAY, FEBRUARY 20.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Gordon V. Childe: Ancient Crete and the Myths of the Greeks.

MONDAY, FEBRUARY 22.

KING'S COLLEGE, at 5.30.—Prof. A. S. Eddington: The Constitution and Evolution of the Stars. (Succeeding Lectures on February 24 and March 1.)

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL, at 5.30.—Prof. D. Murray Lyon: Some Principles of Therapeutics. (Succeeding Lectures on February 23 and 24.)

TUESDAY, FEBRUARY 23.

GRESHAM COLLEGE, at 6.—A. R. Hinks: Astronomy. (Succeeding Lectures on February 24, 25, and 26.)

WEDNESDAY, FEBRUARY 24.

SCHOOL OF ORIENTAL STUDIES, at 5.15.—Prof. E. Herzfeld: Persian Archæology (James G. R. Forlong Lectures). (Succeeding Lectures on March 3, 8, and 12.)

FRIDAY, FEBRUARY 26.

MUNICIPAL TECHNICAL SCHOOL, BIRMINGHAM, at 7.15.—Dr. J. Newton Friend: Historical Chemistry: Phlogistic Period and Joseph Priestley.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Dr. H. T. Calvert: The Activated Sludge Process of Sewage Treatment (Chadwick Lecture).

SATURDAY, FEBRUARY 27.

Problems of Immunity and Infection: the Filter-passing Viruses.

In investigations on the effects produced in the body by invading micro-organisms, much attention has been directed towards an analysis of the defensive reactions of the former, but fewer observations have been made with regard to the offensive powers of the latter. Thus it is well known that the leucocytes or white cells of the blood, the wandering cells of the tissues, and certain of the endothelial cells lining the blood capillaries, are a part of the defensive mechanism of the body against bacteria or other particulate matter, which they ingest, and, if possible, destroy, whilst a further line of defence is represented by the different types of immune bodies which are present in the cells and tissue fluids or are developed therein in response to the invasion. The factors on which the infectivity, or virulence, of an organism depends are, however, less certainly understood, although variations in virulence quite apart from variations in the defensive powers of the host have been frequently observed. The "Report of the Medical Research Council for 1924–1925" lays stress on this aspect of the question, which has assumed considerable importance from the recent work of Gye and Barnard on cancer.

It has been known for some time that certain organisms are, by themselves, non-virulent: thus, the bacilli or spores of tetanus, or lockjaw, and those of gas gangrene, if thoroughly washed, produce no ill-effects on injection into the animal body. Gye and Cramer found that a minute quantity of a calcium salt, or of silica, both common constituents of the soil in which the organisms occur, injected along with them enabled them to act with their full virulence. A somewhat similar relationship was observed by Gye and Kettle with regard to the growth of the tubercle bacillus in the presence of silica, a relationship which is seen clinically in the association of pulmonary tuberculosis with silicosis in 'miners' phthisis.' It is of interest that some protozoa also seem to require the presence of some associated factor before they become virulent: thus, Dobell has found the *Entamœba histolytica*, the amœba responsible for one type of human dysentery, in the intestine of many people in Great Britain, yet the disease itself is very rare.

It will be recalled that the work of Gye and Barnard on cancer offers a very close analogy to the above-mentioned examples of the association of an organism with some 'specific' factor necessary for the development of the power of infectivity. The difficulty facing the hypothesis of the infective nature of cancer has always been the impossibility of transferring the tumour from one animal to another of a different species, and even in the case of animals of the same species, transference is only possible with the living tumour cells. On the other hand, the microscopical appearances of a single variety of cancer in different species are the same, suggesting definitely a similarity of origin. The investigations of Gye and Barnard reconcile these two points of view by showing that the disease depends on the presence of a micro-organism acting in association with a 'specific' chemical factor.

Although usually the inoculation of an animal with a tumour only produces a growth when the living tumour cells are implanted, a few exceptions to this statement are known; thus, the Rous fowl sarcoma is caused by an agent which passes through the finest filters and has for long been believed to be a filter-passing micro-organism. Gye proved that this virus is actually corpuscular, since it can be shifted in fluids by the application of a centrifugal force and in pure culture, in the technique of which he was also successful, can be photographed by means of ultra-violet light by the method devised by Barnard. The presence or absence of the organism, determined experimentally by Gye, was confirmed microscopically by Barnard, thus increasing confidence in the results obtained by each author. But the greatest interest, perhaps, lies in the demonstration that the organism itself failed to produce any tumour when inoculated into fowls: it was only when an extract of tumour tissue in which there were no living organisms was inoculated together with the virus that a growth appeared. It was found on further work that the microbe could be obtained from other animals or tumours, but that the second non-living factor was 'specific,' in the sense that the type of tumour and its actual occurrence in an inoculated fowl depended upon the former's presence. The work suggests that the organism can only produce a tumour when the 'soil' is suitable for its growth: the many agents to which the origin of different cancers is ascribed, such as various irritants, may perhaps act by production of a favourable 'soil,' in other words, by causing the cells of the tissues to form, in the course of their, probably abnormal, metabolism, a chemical substance, which, in the present state of our knowledge, can only be described as the 'specific factor.'

The work of Gye and Barnard lends additional importance to investigations of the other filter-passing viruses and the diseases caused by them, among which may be mentioned canine distemper, 'sleepy sickness' (*Encephalitis lethargica*), herpes, vaccinia (cowpox) and variola (smallpox). That methods which are used for the investigation of the properties and effects of ordinary bacteria are applicable to the study of these viruses has been shown in the case of vaccinia and variola by Gordon. He has found that different samples of vaccine lymph obtained from calves and used in the vaccination of human beings against smallpox contain the same virus, and that the viruses from different smallpox epidemics tested against anti-vaccinia serum, all gave positive results. The fact that the immunity reactions given by this group of 'ultra-microscopic' organisms are similar to those given by the more common bacteria suggests that investigations on the other filter-passers, such as the viruses of cancer and canine distemper, can be undertaken with the hope of adding greatly to our knowledge concerning them. Work in connexion with the latter disease is being carried on in association with the *Field* Distemper Fund. It has been found that the disease can be transmitted to ferrets, which may thus be used for much of the experimental work; the virus is undoubtedly a filter-passer, although it has not yet been isolated or cultivated *in vitro*; the disease is extremely infectious, and it appears possible that the virus is air-borne, at any rate over short distances, necessitating adherence to a scrupulous technique on the part of all those concerned in the investigation.

Two further points may be very briefly considered. Although the chemical nature of Gye's 'specific factor' is quite unknown, there is no reason why further research should not throw light upon its general chemical properties, in the same way that recent work has brought an increased knowledge of the chemistry of the compounds involved in the immunity reactions of the body. Dudley and Laidlaw have obtained from tubercle bacilli a substance which forms precipitates in high dilutions with the serum of animals immunised against the whole protein constituents of the bacilli, although it will not itself evoke the production of such a serum. On analysis, the substance was found to be a complex carbohydrate of the nature of a gum, yielding pentoses and a more resistant nucleus on hydrolysis. Again, Hartley has shown that certain of the reactions between diphtheria toxin and antitoxin are caused by the ether-soluble constituents of the serum, whereas others occur independently of this fraction.

Finally, mention should be made of the question of treatment: the work on the filter-passing viruses having shown their close relationship with the microscopic bacteria, so far as the responses of the body are concerned, the outlook for a specific therapy is brighter than might otherwise have been the case. Meanwhile, the investigation of chemical compounds with a bactericidal action is being continued, especially in connexion with tuberculosis: both sanocrysin and certain oils have claimed the particular attention of numerous workers. An interesting point in connexion with the latter is the discovery by Griffith that the germicidal power of the oils is increased by exposure to the sun's rays, owing to chemical changes which they undergo in the light. One may recall the formation of the anti-rachitic vitamin in similar circumstances, and the beneficial effects of sources of the fat-soluble vitamins in this disease.

The many points on which our knowledge of micro-organisms is advancing suggest a hopeful outlook with regard to the treatment of cancer and tuberculosis, two of the great scourges of mankind. Although a certain cure is not yet obtained, and may be still far distant, a cautious optimism with regard to the position appears to be justified.

Spitsbergen Papers.

Spitsbergen Papers. Vol. 1. Scientific Results of the First Oxford University Expedition to Spitsbergen (1921). Pp. xi+454+17 plates. (London: Oxford University Press, 1925.) 30*s*. net.

BRITISH tradition in Spitsbergen dates from Stuart times, when English sailors explored the coasts and fiords of that northern land. Later, Phipps, with whom was the midshipman destined to be Lord Nelson, and Lord Dufferin, added to our associations. Scientifically, however, the tradition is barely half a century old, Sir Martin Conway's expedition being virtually the first serious attempt of British men of science to grapple with the problems—geographical and geological—of Spitsbergen. Within the last few years, the exploration work of the late Dr. W. S. Bruce, the detailed geological investigations of the Scottish Spitsbergen Syndicate, and the results of the several Oxford University expeditions, have put the seal upon our interest and research.

The present work, which is the first volume of the results of the four Oxford expeditions and is devoted to the researches of the first (1921) party, consists of thirty-two reprints of papers, retaining the format and pagination of the scientific journals in which they originally appeared, with an appendix on Polyzoa and Tunicata which has not previously been published.

In the preface to the volume, the writer states that the original idea was that the expedition should be purely ornithological. Later, however, the personnel was increased to include representatives of the other natural sciences, with the result that the book contains articles on subjects ranging from rotifiers and lichens to topography, glaciology, and the courtship of birds. The party finally consisted of eighteen men under the leadership of the Rev. F. C. R. Jourdain, and with the title of the Oxford University Expedition to Spitsbergen.

The expedition consisted of two parties which spent almost three months in the archipelago, visiting Bear Island, Prince Charles Foreland, and the west coast of Spitsbergen generally, and Ice Fiord in particular. The scientific results obtained were published as soon as possible in the appropriate journals, so that specialists have already seen the results that most concern them.

The results may be divided into two groups: those which deal with topographical and geological work, and those concerned with the zoological and botanical observations made by the expedition. The former is represented by three papers of great interest. Mr. R. A. Frazer gives an account of the topographical work of the expedition, which was mainly in the nature of a reconnaissance and consisted principally of a sledge journey into the area north-east of Ice Fiord known as Garwoodland and New Friesland. In another paper Messrs. Huxley and Odell describe in detail the nature, and their theories of the formation, of the peculiar stone and fissure polygons and other surface markings seen so well in Spitsbergen. This paper is of special importance in view of the fact that it was only so recently as 1914 that Högbom, for the first time, put forward a feasible explanation of the phenomena. Mr. Slater's observations on the Nordenskiöld and neighbouring glaciers are also worthy of close study in view of the analogies (already noted by Garwood and Gregory) to be drawn between certain glacial phenomena in Spitsbergen and British drift deposits.

The biological papers are of exceptional interest from an ecological point of view. Spitsbergen occupies a peculiarly favoured position for such study, being a fairly accessible region for the explorer, yet sufficiently isolated to maintain a relatively simple fauna and flora. In addition, a great number of observations had already been recorded by other workers. Full advantage was taken by the Oxford Expedition of the opportunities thus afforded, as is evidenced by the published results. In a work of this kind, it is an invidious task to select papers of outstanding merit, but the "Contributions to the Ecology of Spitsbergen and Bear Island" by Messrs. Summerhayes and Elton is one of the most striking contributions yet made to Arctic biology. In this paper the authors describe the plant and animal communities of part of Bear Island and Spitsbergen (Prince Charles Foreland, Cape Boheman, and various parts of Ice Fiord). The succession of plant communities is traced, a noteworthy feature being the relative abundance of cryptogams, especially Bryophyta. The proportion of this group is particularly high upon the maritime coasts, which is no doubt due to the increase in humidity. The number of species, both plant and animal, is small, the severity of climatic conditions, geographical isolation, and the absence of distinct night and day being the chief factors held responsible. In addition, the authors give a sketch of the food cycle in Bear Island.

The remainder of the papers, apart from a few on ecological problems, are devoted to additions to systematic zoology and botany.

The volume, since it unites a somewhat scattered literature, will prove useful to libraries, universities, and other institutions, besides appealing to the ever-increasing number to whom Spitsbergen is more than a geographical name. The absence of an index in a work like this is of no real importance, but one hopes that the printers, not the authors, are responsible for the occasional lapses in the spelling of geographical names and for the 'die-hard' form "Spitzbergen," which once or twice makes its way into the text.

The results of the further Oxford expeditions will appear as the second volume of these papers, while other results, notably ornithological, will appear in book form. Perhaps one can say nothing better for the present part than that one looks forward with interest to the arrival of these future works. In the preface, the committee expresses the hope that other young scientific workers may have equal opportunities for similar experience. All who read these results will heartily echo this wish. Few countries offer so much of value for the young natural historian as Spitsbergen, and the work of the Oxford expeditions will prove an admirable guide. W. E. Swinton.

Products from Coal.

The Industrial Applications of Coal-Tar Products. By H. M. Bunbury and A. Davidson. Pp. xi + 284. (London: Ernest Benn, Ltd., 1925.) 42*s.* net.

The numerous products obtained from coal-tar are ever increasing in importance, not so much, perhaps, because of the isolation of new substances or new derivatives of the older materials recognised as being present therein, but more by reason of the utilisation of compounds hitherto known to be present, which have previously found no industrial application. In the preface to the book under review, the authors direct attention to the fact that no commercial use has yet been found for phenanthrene and fluorene, and it is indeed remarkable that this should be the case when it is remembered that phenanthrene is the basis of some of our most important natural alkaloids. Nevertheless, the other side of the picture tells a different story, and there can be no question that in the near future use will be found for these hydrocarbons just as use has now been found for such substances as acenaphthene and carbazole, compounds at one time regarded as laboratory rarities.

The materials required by the chief users of the coal-tar products, the fine chemical industry and the dyestuffs industry, are steadily advancing in complexity and intricacy, because the competition between the various interests leads to the production of new compounds possessing some small advantage over the older ones which enables them to compete successfully in the world's markets. It does not necessarily follow that complexity of structure implies commercial advantage, because some of the simpler products—for example, aniline black—still retain their places among the foremost of the dyes in use. But when the field of choice is so wide and the number of products so great, research will always find some particular substance which has special industrial advantages leading to a demand for its production, and the manufacturer is often prepared to meet this demand even though it entails a financial loss.

The progress of the dyestuffs industry, which is based on the products from coal-tar and the "intermediates" derived from them, is indicated by well-defined steps, each involving the utilisation of a new series of products. The initial production of the triphenylmethane dyes found employment for the coal-tar bases aniline, the toluidines, and so forth. The introduction of the substantive cotton dyes provided a use for naphthalene and the sulphonic acids of the naphthols and naphthylamines. The production of synthetic alizarine brought in anthracene and the tremendous step in advance made when Bohn discovered indanthrene provided a use for a variety of products hitherto either unknown or not utilised. Without question, the development of the industry depends on the production of new and suitable intermediate products or the preparation of old "intermediates" in a new and more economical manner, and it would seem that we are now about to enter a new era in this connexion which may affect our existing conditions of manufacture, because it entails a completely new kind of chemical technique.

The successful production of methyl alcohol (methanol) provides the "writing on the wall" and indicates the direction synthetic organic chemistry will take in the future. Every manufacturer interested in organic chemical reactions, and every organic research chemist, should keep the phrase "reactions at high temperatures and pressures in the presence of a catalyst" always before him, because we as a nation must not be behindhand in the new development.

The book under review is a well-thought-out attempt to group the industrially important material among the dyestuffs, explosives, and so forth, under the head of the industrial parent substance. The method is a good one, and enables the reader to find with little trouble any substance concerning which he may require information. The use of charts wherever possible facilitates reference and helps the reader to see at once the relationship between the various derivatives of some single parent substance. For example, Chart v. on pp. 116 and 117 gives a very clear and concise picture of the derivatives of naphthalene. The book is well printed, and the formulæ are clear and not too elaborate. It should find a place on the shelves of all those who are interested in the subject with which it deals. J. F. T.

South American Pit-Vipers.

A General Consideration of Snake Poisoning and Observations on Neotropical Pit-Vipers. By Afranio Do Amaral. (Contributions from the Harvard Institute for Tropical Biology and Medicine, 2.) Pp. vi+64+16 plates. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1925.) 10*s.* 6*d.* net.

THE work under notice is a collection of four papers on the classification of the South American pit-vipers, prefaced by an essay on snake poisoning in general. In the preface, the nature of the poisons of the principal venomous snakes, their complexity, their action, the quantity of venom ejected, the symptoms seen in victims bitten by serpents of different kinds, and the serum treatment of snake bite is all surveyed in 20 pages. The materials for this survey have been selected with discretion, the information is accurate, and it forms a useful introduction to the subject of snake poisoning, but has no particular relation to the four short papers which follow it.

Of the serum treatment of snake poisoning, the author has had first-hand experience at the Butantan Institute at Sao Paulo, where he has been an assistant for some years. The Butantan Institute is the only place where the serum treatment of snake poisoning has been thoroughly exploited, first by Vital Brazil and latterly by Gomes. Here four classes of serums—anti-crotalic, anti-micrurus, polyvalent anti-bothropic, and polyvalent anti-ophidic—are manufactured and issued in concentrated form. Snake poisons are highly specific, and a serum produced against one species of snake is generally of little use against another, although some amount of overlapping occurs. Polyvalent sera are, therefore, necessary for treatment, as the particular species of serpent responsible for the bite cannot usually be identified and there is no time to spare, if the treatment is to be effectual.

As with poisoning by bacterial toxins, early administration of serum is essential. We do not agree with Dr. Amaral that the dosage and method of administration should be adapted to the "estimated" quantity of poison inoculated. We believe this to be dangerous advice, and that a full dose should be administered as soon as possible after the accident and by the intravenous route. If this is impracticable, the serum should be injected deeply into the muscles of the buttock. Anti-serum is but slowly absorbed from the subcutaneous tissue, and is at least twenty-five times as effective when injected directly into the circulation. Unfortunately, intravenous injection is rarely possible until some time afterwards, as the doctor is not usually present at the time of the accident. Notwithstanding all the disadvantages pertaining to the treatment of snake poisoning, the results in Brazil have been very encouraging.

The value of the preface would have been increased if a short bibliography had been attached to indicate to the serious student where the literature on snake poison may be found. Should such a one read this review, he may be glad to know that it is completely reviewed in vol. 2 of Marie Phisalix's wonderful book, "Animaux venimeux et venins" (Paris: Masson et Cie, 1922).

The four systematic papers contain a reasoned criticism of the present classification of the commoner pit-vipers and suggestions for their better arrangement, based upon the examination of upwards of 6000 living specimens of all ages. It may seem strange that one individual has had such a wealth of material at his disposal. This is explained by Dr. Amaral's connexion with the serum institute at Butantan, Brazil. Quantities of living snakes are procured by the Institute to supply venom for the immunisation of horses, and many are also sent for identification in order that the victim of snake bite may receive the appropriate anti-venom.

A re-examination of the classification of these South American vipers will be welcomed by herpetologists and others interested in their identification, as at present there is some confusion. The wealth of synonyms, too, is bewildering. In the British Museum catalogue of snakes, under *Lachesis lanceolatus*, there appear more than thirty synonyms. Dr. Boulenger, who is responsible for the catalogue, does, indeed, suggest that, under this designation, two or three different species may be confounded. In the opinion of Dr. Amaral, much of the confusion is due to the fact that European herpetologists have generally had only spirit specimens at their disposal, which had lost their colour, and have not had means of differentiating young from old snakes. As he shows in the second article in the book under review, "On the Evolution of Dorsal Markings," the pattern at different ages varies so greatly in some species, *e.g. Bothrops jararacussu*, that it might be supposed that one was dealing with different species.

The principal paper in the series is on the differentiation of the species *Bothrops atrox*, *B. jararaca*, and *B. jararacussu*. The author concludes that "echis" of most of the Spanish-American countries, the "fer-de-lance" of Martinique, the "barcin" of Trinidad, and the "caissaca" of Brazil are all one species, *Bothrops atrox* (Linné). The "jararaca" of Brazil and the "yarara" of the Argentine he found to be *B. jararaca* (Wied), and the "jararacussu" of Brazil and the "yararaguassu" of Argentine, Paraguay, and Bolivia to be *B. jararacussu* (Lacerda). He prefers the generic term "Bothrops" to that of "Lachesis," on the ground that this name was the first used, namely, by Linné so long ago as 1758. The three species differ in their habits of life. *B. atrox* prefers humid, wooded, and rocky places, and feeds on small rodents. *B. jararaca* prefers the open and is commonly encountered in hay-fields. It also devours small rodents. *B. jararacussu* is amphibious and feeds almost exclusively on batrachians. Their poisons are different. These three species are described in detail. The last of the series of papers deals with *Bothrops Neuwiedii,* which Dr. Amaral proposes to divide into four subspecies, on the ground of the fixity of their chromatic characters. Here he would appear to be on uncertain ground. The characteristics on which the proposed subdivision is based are associated with the habitat of the snakes, and there is no evidence that if they were translated from one locality to another the supposed fixity would be maintained.

The papers are accompanied by excellent plates. The coloured pictures of *B. atrox, B. jararaca,* and *B. jararacussu,* drawn from life, are beautiful.

C. J. M.

The Newcomen Society.

The Newcomen Society for the Study of the History of Engineering and Technology. Transactions, Vol. 4, 1923–1924. Pp. xii + 153 + 21 plates. (London: Secretary, Newcomen Society, Science Museum, 1925.) 20*s.*

THIS latest volume of *Transactions of the Newcomen Society* is one of wide interest. The subjects dealt with range from chain pumps of the seventh century to the earliest locomotives in America; from the dynamics of Leonardo da Vinci to the bibliography of the history of engineering and applied science. As a frontispiece there is a reproduction of the earliest known print of a Newcomen engine. This print is not only the earliest drawing, but also the earliest document of any kind known showing the construction of the engine. The original by Henry Beighton was only recently discovered in the Library of Worcester College, Oxford, by Mr. L. de M. Johnson, of the Oxford University Press. Though in the *Transactions* the drawing has had to be folded, copies can be obtained unfolded, and we think this historical drawing should be exhibited wherever mechanical engineering is taught.

The philosophical view of the work of the Society is well stated in the presidential address of Mr. Loughnan St. L. Pendred, while the biographical side is illustrated by a paper on the Rastricks—a family in which engineering skill was in some degree inherited. John U. Rastrick was a contemporary of George Stephenson, and his best memorial is the London and Brighton Railway.

Just as it is the aim of the Newcomen Society to further the study of the history of engineering and technology, so it was one of the objects of the Royal Society in its earliest years to collect and chronicle a history of the minor arts and trades. In his diary of January 16, 1660, John Evelyn wrote: "I went to the Philosophic Club where was examined the Torricellian experiment. I presented my circle of Mechanical Trades"; and in Dr. Birch's History of the Royal Society is an entry of the same date: "The Catalogue of Trades brought in by Mr. Evelyn and that of Dr. Petty were referred to them and Dr. Merret to be compared, methodised and returned to the Society." Evelyn's "Circle" has been preserved, and with a prefatory note by Mr. Forbes Sieveking is reproduced in this volume.

Two very different aspects of the iron industry in England are given in Mr. Rhys Jenkins' "Sketch of the Industrial History of the Coalbrookdale District," and in Mr. W. A. Young's paper, "Works Organisation in the 17th Century: some account of Ambrose and John Crowley." Iron founding has been carried out in the Coalbrookdale district for centuries, and here the problem of smelting iron with coke was solved, cast-iron tram lines first used, the first cast-iron bridge erected, and some of the cast-iron cylinders made for Watt's engines. The blast furnace made its appearance in Shropshire about the middle of the sixteenth century, and from 1707 until 1791 the three Abraham Darbys in succession reigned over the Coalbrookdale works.

The Crowleys began as ironmongers in Greenwich and in London, and then became manufacturers of hardware in Durham. The firm was in existence for 170 years, and the picture of the works at Winlaton, where edge tools, files, anchors, nails, spades, etc., were made in very large quantities, is one of a community somewhat resembling that of a great religious house. Innumerable rules were laid down to encourage and admonish, courts of arbitration met at stated intervals, the children were educated, the sick doctored, and the infirm pensioned. Working hours were from five in the morning until eight at night, and curfew rang at nine o'clock. The instructions went so far as to provide for the assistance of those who, by reason of "folly, weakness or extravagance," have had recourse to the pawn shop. Sir Ambrose Crowley died in 1713, a very wealthy man. He had been an alderman and sheriff of the City of London, but Mr. Young's paper shows that he is entitled to be considered the pioneer of industrial welfare work. He made a very remarkable experiment, and the principles laid down by him sufficed for guidance for more than a century.

Our Bookshelf.

The Rigid Airship: a Treatise on the Design and Performance. (The Specialists' Series.) By E. H. Lewitt. Pp. x+283. (London: Sir Isaac Pitman and Sons, Ltd., 1925.) 30*s.* net.

THE airship in aeronautical text-book literature has received but scant attention in the past. Aeroplane and seaplane design and the theoretical problems associated with them compose the subject matter of such works, while airships are dismissed in a few meagre paragraphs under the general heading of "lighter-than-air craft." There is no special reason for this other than that the airship has almost consistently been regarded as the step-child of officialdom and certainly not to be encouraged by any consistent policy of construction and development. Yet, regarded as a scientific problem, the design of the rigid airship, as the present work proves, presents a problem in a type of structure which has not previously occurred in engineering and consequently gives rise to a crop of fresh problems both on the aerodynamic and the structural sides.

The present work is confined to the question of design on the structural side. The earlier chapters analyse the forces on the airship in so far as they affect this question. The types of girders and struts used and the elastic properties of which they are composed are described in Chap. iv. The next two chapters treat of the beam stresses and the temperature stresses in the hull. The author then passes on to consider the tensions in the wiring—transverse, circumferential, and diagonal—and the longitudinal girders. The treatment is completed by a discussion of performance and a detailed analysis of design in a special case.

The author has throughout adopted the sound method of approaching each problem mathematically and comparing the results so obtained with actual experiment. In this respect the treatment is excellent. If a criticism might be offered, it is that the author has tended to keep rather closely to the methods developed in his own contributions to the subject, so that the work of other investigators is scarcely accorded sufficient prominence; otherwise a most satisfying book.

The British Journal Photographic Almanac and Photographer's Daily Companion, with which is incorporated "The Year Book of Photography and Amateurs' Guide" and "The Photographic Annual," 1926. Edited by George E. Brown. Pp. 848+32 plates. (London: Henry Greenwood and Co., Ltd., 1926.) 2*s.* net.

As this is the diamond jubilee issue of this well-known publication, the editor has considered it a suitable time to make several improvements in it, though a cursory glance shows that it is similar to previous issues in the general nature and arrangement of its contents. There are three notable changes in addition to the use of a rather clearer type. It is no longer an almanac except in title, for it contains nothing of the nature of an almanac or calendar. What was originally subsidiary matter has increased so much that the volume is now a general practical guide and record of progress, and in due time, we suppose, the main title will indicate this. For many years a substantial part of the matter other than the advertisements was a collection of short articles from many contributors giving their experiences and suggestions. This section served its purpose at the time, but changing circumstances rendered it advisable to discontinue it. This year there is tendency to return to it; but the five articles are rather of the review or generally instructive character than of a personal nature. The history of the "Almanac," with a reproduction of the first, which was a wall sheet calendar with a few useful items of information in the margins, is of value from a historical point of view. The editor on "Amateur Cinematography," Mr. T. L. J. Bentley on the use of a hand-camera, and Mr. J. W. Purkis on "Rational Time Development" are authoritative articles on matters of present-day interest. As a celebration of the jubilee the volume includes thirty-two excellent photogravure reproductions, twenty-five of which are from the Paris Salon of Photography.

Electrical-Machinery Erection. By Terrell Croft. Pp. ix+314. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 15*s.* net.

MR. CROFT is concerned with the mechanical features of electrical machinery installation. The average young engineer when he has finished his college training knows little of the mechanical operations that have to be performed between the unloading, for example, of a heavy motor generator set, from the car to its final fixing and aligning in its operating position. As a rule, he allows himself to be guided by the foreman, who generally does everything by a cut-and-dried method. The methods of arranging the slings and of bracing the apparatus prior to lifting he learns from the workmen. The methods learnt in this way are unsuitable in certain cases, and the young engineer is too often thrown on his own resources, sometimes with unfortunate results. We therefore welcome this book, as it should prove useful to every engineer engaged in erecting work. There are 334 excellent illustrations, showing not only the correct methods, but also commonly used incorrect methods, of performing necessary mechanical operations. A section of the work is devoted to "mechanical maintenance," particular attention being devoted to the upkeep of the bearings.

The Dynamical Theory of Gases. By Dr. J. H. Jeans. Fourth edition. Pp. vii + 444. (Cambridge: At the University Press, 1925.) 30*s.* net.

THE intervals at which new editions of this valuable treatise are called for grow shorter, testifying to the continued—in fact, growing—interest of students and investigators in the subject, and to the importance of the service rendered by the author in presenting it so admirably. The second edition, of 1916, was different in important respects from the original work of 1904, the quantum theory having in the interval offered a way of escape from the difficulties surrounding the theorem of equipartition of energy. In the third edition, of 1921, the account of the quantum theory was extended. In the present issue a few recent papers on the kinetic theory are duly remarked on, either in the text or in footnotes, but no important changes are made.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Law of Inertia for Radiating Masses.

RADIATION of amount δE, lost by a body, diminishes its effective mass, on Maxwellian principles, by $\delta E/c^2$: and some perplexity is apparent in recent discussion as to how this tells on the dynamical inertia of a planetary mass. According to the Newtonian doctrine, it is the rate of change of momentum mv which must be equated to the extraneous gravitational or electric force acting on the body: and this principle was taken over by Einstein, in extended fourfold form and in concert with relativity, as the key to his brilliant tentative explorations towards a closer view of gravitation. But

$$\frac{d}{dt}(mv) = m\frac{dv}{dt} + v\frac{dm}{dt};$$

so that if the mass is diminishing by radiation, conservation of momentum seems to demand acceleration of velocity of a body isolated and so free from external force. Yet the doctrine of relativity asserts that no standard can exist on which to measure such change of velocity, whether of translation or rotation: such a conclusion therefore would contradict relativity. On this ground it is claimed that the applied force must be equated, following Dr. Jeans, to $m\frac{dv}{dt}$ and not to $\frac{d}{dt}(mv)$. Yet the latter form is based directly on a very keystone of relativity. One way out of the apparent paradox would be to postulate a frame in the ether with reference to which the velocity of an isolated body could be measured: this would institute an exception to accepted doctrine widely verified. Prof. E. W. Brown (*Proc. U.S. National Academy*, 1926, p. 2) appears to be troubled, and naturally so, by uncertainty as to which formula to adopt with a view to studies on cumulative long-range effects of radiation in dynamical astronomy.

It seems well worth while, in this connexion, to direct attention to a classical memoir by the late Prof. Poynting (*Phil. Trans.*, 1903) on "Radiation in the Solar System" and to his other investigations, theoretical and experimental, on pressure of radiation, in which astronomical effects are considered. In particular, he revealed (by indirect argument) what amounts to the Bradley aberration effect in pressure of extraneous radiation on a moving body: and he showed that it produces a retarding force that would in times quite short geologically suck all small bodies such as cosmical dust revolving steadily round the sun, into that luminary. This is doubtless the explanation, as he remarked, why the celestial spaces are so transparent. Incidentally it may perhaps require that the cosmic dust that reflects the zodiacal light should have some source of replenishment.

This, however, is not directly connected with the inertia question. But in the reprint of Poynting's "Collected Papers" (Cambridge University Press, 1920), the question of the effect of diminution of inertia by radiation had to be gone into, in the notes and corrections then appended to the work, as on the face of things it may be quite comparable in importance (for large masses) to the deflexion of the radiation pressure by aberration. The explanation proceeds on the principles of Maxwell's great "Treatise" of 1873, without any reference to relativity. It is in effect verified (pp. 434, 754-7, referring back to "Math. Congress Report," Cambridge, 1912) that the momentum of the whole system, matter *plus* radiation, is conserved, as it ought to be, in the absence of any extraneous force; but a part of its gradient equal to $v\frac{dm}{dt}$, where $\delta m = -\delta E/c^2$, is momentum carried away by the radiation δE issuing from the system, by the mechanism of radiation pressure, while it is the remainder $m\frac{dv}{dt}$ that is to be equated to the extraneous force, which acts on the material system itself, not on the radiation that has escaped from it.

This seems to be the adequate practical settlement of this question, and may, it is hoped, encourage Prof. Brown to proceed with closer astronomical investigations in improvement of Poynting's pioneer indications: though how far it consorts with an extreme relativist position is a different question. But Poynting's retardation by the aberration influence on pressure of radiation will also have to be taken into account in the cosmical problem of the evolution of the orbits of a double star, as probably of the same degree of importance as change of effective mass by loss of radiant energy.

In Poynting's own special problem there is no change of mass (other than that involved in high velocity in accordance with Least Action), as the loss by radiation is made good by absorption from the sun.

JOSEPH LARMOR.

Cambridge, February 9.

The Structure of Molecules.

WITHIN the past few months there have appeared several papers on band spectra containing results of great theoretical significance. Taken in connexion with the data given in my letter to NATURE of February 13, p. 229, on the energy levels of the carbon monoxide molecule, they appear to indicate a comprehensive analogy between the electronic energy levels of molecules and of atoms. The additional evidence furnished by the rotation and vibration of molecules then makes possible conclusions as to the actual paths of the valence electrons in molecules, and these results may in turn be used as evidence as to the structure of atoms.

Some of the investigations leading up to this situation are as follows. Mulliken (*Phys. Rev.*, 26, 561, 1925) has shown clearly the existence of two types of multiplicity in the band spectra given by diatomic molecules. One type is essentially a function of the rotation of the two nuclei about their common centre of gravity, and has no counterpart in atomic structure. It is not concerned in the present discussion. The other type is essentially independent of rotation and of vibration, and, as Mulliken has pointed out, leads to multiple electronic energy levels in the molecule which may be correlated with the multiple levels of atoms. Thus in the "odd" molecules CO^+, BO, CN, and NO, there is a double level which may be designated as a double "*p*" level. Mulliken (*Phys. Rev.*, 26, 1, 1925) has found such a double level also in the alkaline earth halides, and has noted that the doublet separation is of the same order of magnitude as in a certain "corresponding" atom, having the same number of valence electrons. Mecke (*Naturwiss.*, 13, 698 and 755, 1925) independently pointed out certain analogies between BO, CO^+, CN, and N_2^+, and investigated also the alkaline earth halides. For these latter he applied the Landé formula for the doublet separation in the alkalies, and thus obtained an "effective quantum number," and an "effective nuclear charge," for the orbit of the valence electron of the molecule. The result indicated considerable "penetration" of the electron. Hulthén (NATURE, 116, 642, 1925) found doublet separations in HgH, CdH, and ZnH, which are of the same order of magnitude as a certain p separation in Hg, Cd, and Zn.

In the present communication I am considering particularly diatomic molecules with two atoms of more or less equal mass, such as CO, CO^+, N_2, N_2^+, NO, CN, and BO. For such molecules Mulliken has assumed that each atom retains its own K electrons, but that the remaining electrons are held in common by the two atoms, and may have much the same arrangement as in atoms. In the above molecules there are thus eight electrons with a rare gas configuration, plus one, or two, or three "valence" electrons, and the molecular structure is to be compared with one-, or two-, or three-valent atoms In CO^+, CN, and BO there are, in addition to the double p level, two single electronic levels, one above and the other below the p level, and Mulliken suggested that they might be called s levels. This suggestion resulted from an analysis of the character of the band systems associated with the s-p, s-s, and p-s transitions. (The reader is reminded that an entire system or group of bands corresponds to an electron transition between two major electronic levels, and hence to a single "line" or, more generally, to a single "multiplet" of atomic spectra. All three of the transitions just noted are known in CO^+ and BO, with the s-s transition giving the strongest band system. See Birge, NATURE, 116, 207, 1925, and Mulliken, *Phys. Rev.*, 25, 259, 1925.)

Let us now consider the actual "term" values of the electronic energy levels of molecules, defined just as in the case of atoms as proportional to the work required to carry the valence electron from the level in question to infinity. There are as yet but little data for such calculations, accurate values of the ionisation potential of molecules being especially scarce. CO, N_2, and H_2 are, however, three sources of possible information. The designation of successive levels as X, A, B, C, X', A', etc., as used in my letter on carbon monoxide, is retained here.

Using X'-X in carbon monoxide as 14·2 volts, as discussed in this letter, and writing $\nu = R/D^2$, where R is the usual Rydberg constant, and D the "denominator" of the term ν, one obtains for the X, A, and B levels, values of D of 0 98, 1·48, and 1·97. In this case all three terms are single, and since carbon monoxide should "correspond" to magnesium, the results immediately indicate that these energy levels are really the $1S$, $1P$, and $2S$ levels of the molecule, where $1S$ and $2S$ fit into a *Rydberg formula*. Sponer (*Zeit. f. Phys.* 34, 622, 1925) has noted from my diagram of the energy levels of N_2 (NATURE, 114, 642, 1924) that A, C, and D fit a Ritz formula, giving very closely the observed value of the ionisation potential. I now find that A is a triple level of spacing approximately 20 and 42. The spacing of the $1p_{123}$ level of the "corresponding" atom Mg is 41 and 20. The C level of N_2 is undoubtedly triple, with intervals roughly of two units. The $2p_{123}$ level of Mg has a spacing probably of 4 and 2. For the $1p_{123}$ level in N_2 the order of spacing is inverted, as compared to that for the atom, and Mulliken has noted, from the relative intensities in the molecular double p level, that it also is "inverted."

In the helium molecule it has long been known that there is a set of electronic energy levels given by the ordinary Rydberg formula (Fowler, *Proc. Roy. Soc.*, A, 91, 208, 1915; see also Curtis and Long, *ibid.* 108, 513, 1925), and in the hydrogen molecule there is a similar set of levels, running to the limit 16 68 volts, which is a reasonable value of the ionisation potential of H_2. This interpretation of the Olson and Glockler results (*Proc. Nat. Acad. Sci.*, 9, 122, 1923) is due to Olson (see Urey, *Proc. Nat. Acad. Sci.*, 11, 618; 1925). Hence in *all* molecules where data are available, we find series of energy levels fitting at least approximately into the customary formulæ of *line spectra*. It therefore seems to me that the time has come to make the following generalisation, which is admittedly based on data only for a few diatomic molecules, confined to definite types.

The energy levels associated with the valence electrons of molecules agree in all essential aspects with those associated with the valence electrons of atoms. The molecular levels may be designated s, p, etc., and levels of the same letter-designation may be represented by the usual formulæ of line spectra, and have the same multiplicity as in the case of corresponding atoms. The actual spacing in the multiple levels is often roughly the same as for the "corresponding" atom. Further examples of this are: for $1p_{12}$ of CO^+, 126, as compared to 91 5 for Mg^+; for the *stable* $1p_{12}$ level of NO, 135, and for the corresponding atom Al, 112. This interpretation of Dr. Sponer's energy levels of NO (NATURE, January 16, p. 81) is due to Mulliken (private communication). In other cases there is no numerical agreement, as in the $1p_{12}$ level of CN and BO ($\Delta\nu = 54$ and 126, compared to 17 for Na). Further points of difference between atoms and molecules are: (1) the multiple molecular levels are "inverted"; (2) s to s transitions in molecules are not only not prohibited, but are especially prominent.

If now the systems of energy levels of the molecule and of a "corresponding" atom are essentially similar, the electronic structure responsible for the two systems must also be essentially similar, as already suggested by Mulliken and by Mecke. But the band spectra data give additional direct evidence as to the character of this structure. Thus in the molecules CO, CO^+, NO, CN, and BO, the frequency of vibration of the dipole for the p state is always *less*, and consequently (from a known invariable relation) the moment of inertia *greater*, than for the s state above as well as below it. Now in an atom, according to current theory, the "penetration" of the electron in the s orbits is greater than in the p orbits. If then the valence electron (or electrons) of the molecules here considered moves in an elongated path which penetrates to the region *between* the two nuclei, the greater penetration of the s orbit would lessen the repulsion of the two nuclei and thus produce a smaller moment of inertia. This gives a picture of the valence electron as one moving in a path which projects beyond those of other electrons, and so gives this electron its valence character, but also penetrates the region between the two nuclei and so plays a definite rôle in determining the strength of the chemical bond. I think that band spectra can thus give evidence as to the character of electronic orbits, the mere existence of which some investigators still seem to doubt.

The above conclusions allow a rough computation of the ionisation potential of CO^+, N_2^+, and similar "odd" molecules, and the results raise many interesting points for which there is no space in the present communication. In particular, the *total* work to remove *both* valence electrons from CO or from N_2 is equal, within the large limits of error, to that required to remove both electrons from Mg, but the work necessary for the removal of the first electron (and consequently for the second) in the case of the molecules is quite different from that for the atom. So far as I can see now, none of the results are inherently unreasonable or in conflict with the present experimental data, and I hope to consider them in detail in the full report of this work.

I have had the benefit of consultation with the many persons in this University who are interested in these problems, and also of much correspondence with Dr. Mulliken. I am especially indebted to Dr. Sponer and to Dr. Mulliken for helpful suggestions.

Effects of Polarised Light on Bacterial Growth.

DURING recent years certain biochemical effects of polarised light as compared with ordinary light have been brought into prominence by Dr. Elizabeth Sidney Semmens (*Journ. Soc. Chem. Ind.*, 42, 954, 1923; also *Bri. Assoc. Rep.*, 1923). She has shown that the hydrolysis of starch proceeds with greater rapidity in polarised light than in ordinary light of the same intensity, all other conditions being identical

In biological studies of bacteria specially with reference to their pathological and epidemiological significance, heat and various other physical conditions such as humidity, etc., have been put up as factors of fundamental importance. So far as the authors are aware, however, very little attention has been paid to the effects on these aspects of bacterial life of the variations of luminous radiations in Nature. The amount of polarisation of light, as is well known, being subject to marked variations not only from season to season and country to country but also during different parts of the day and night, it occurred to the authors to investigate as to how the bacteria would react to polarised light.

So far preliminary experiments on the growth of *V. Choleræ* and *B. typhosis* (strains obtained from Kasauli) have been tried. The results obtained were so interesting that it was considered desirable to communicate them without delay.

Emulsions of young *V. Choleræ* and *B. typhosis* cultures in Dunham's solution and nutrient broth respectively were prepared and thoroughly shaken in a mechanical shaker. Equal amounts of the uniform emulsions so obtained were exposed for a definite period to polarised and unpolarised light of equal intensity in two compartments of a sterilised optically correct cell ordinarily used with a Rayleigh interference refractometer manufactured by Messrs. Adam Hilger. The source of light for both the polarised and the unpolarised beams was a hundred-candle-power half-watt lamp from which two beams of light were obtained by means of a parallelising device. The polarisation of one beam was effected by interposing a Nicol prism in its path, and the intensities of the two beams were equalised by means of glass plates. To test the intensities of the two beams of light, the deflexions produced in a Broca's galvanometer were compared when a Rubens linear thermopile connected to the galvanometer was placed at equal distances in their paths.

The difference in the turbidity of the two compartments after exposure was taken as an index of the difference in their bacterial content. The turbidities were determined by exposing the two compartments successively to a standard source of light (6-volt half-watt Mazda lamp) for half a minute and measuring the intensities of the light, after passing through the cell, by means of the thermopile and Broca galvanometer arrangements described above. The results so obtained were confirmed by plating out 0·5 cc. of the contents of the two compartments on agar and counting the number of colonies in the two cases after forty-eight hours' incubation at 37° C.

Some of the results are shown in the table below. The observations were made at room temperature

Type of Organism	Duration of Exposure	Deflexions of the Galvanometer.		Colonies on Agar.
		Compartment exposed to polarised light	Compartment exposed to unpolarised light.	
V. Choleræ. 24 hours' growth on agar emulsified in Dunham's solution	2 hours	0·80 cm.	1·10 cm.	
Do.	14 "	0·90 "	2·60 "	
B. typhosus. 24 hours' growth in broth . .	5½ "	0·80 "	1·15 "	Innumerable in both. Distinctly larger number in the case of the compartment exposed to polarised light.
Do.	21 "	0·70 "	1·25 "	

These results suggest that the polarised light favours bacterial life as compared with ordinary light of equal intensity.

What rôle the reactions of polarised light on the binomics of the bacteria—free in Nature, in water and in the body of the carrier—play in the mechanism of their pathogenicity and epidemicity seems to involve large issues and is a subject worthy of consideration. It also suggests problems regarding the reactions of polarised light on the physiological and pathological processes in the body of the host which may throw some light on questions such as the afternoon rise of temperature in normal individuals and in certain fevers. Work on some of these problems is in progress.

The Nature of Active Nitrogen.

LE problème de l'azote actif a donné lieu récemment à un certain nombre de travaux. Dans un article récent (*Zeitsch. f. Phy.*, 84, 622, 1925) Dr. Sponer reprenant les premières idées de Strutt, émet l'hypothèse que l'azote actif est de l'azote atomique (voir aussi R. T. Birge, NATURE, 117, 81, 1926).

J'ai déjà montré (*C.R.*, 178, 1966, 1924.—Thèse, Paris, 1925, ou *Ann. de Phy*, sept. 1925) que cette explication des propriétés chimiques et physiques de l'azote actif est la plus simple et la plus logique. Il semble qu'une seule difficulté fasse hésiter les spectroscopistes à admettre l'hypothèse atomique. Au cours de l'activation et de la neutralisation, l'azote n'émet que des spectres de bandes à l'exclusion de tout spectre de raies. Or il est généralement admis que les spectres de bandes ne peuvent être émis que par des molécules polyatomiques. La présence d'atomes dans l'azote actif paraît, dans ces conditions, assez peu vraisemblable. Ainsi s'explique que plusieurs physiciens, à la suite de Saha et Sur (*Phil. Mag.*, 48, 431, 1924) n'aient voulu voir dans l'activation de l'azote qu'une transformation, sans dissociation, de la molécule diatomique en une forme métastable de niveau énergétique élevé.

Or des mesures précises de largeurs de raies faites par Hamy (*C.R.*, 157, 142, 1913) et par moi (*C.R.*, 178, 474, 1924, et *loc. cit.*) ont montré que, si le premier groupe positif de l'azote est effectivement émis par la molécule diatomique de masse 28, le 2^e groupe positif et le groupe négatif de l'azote sont certainement émis par l'atome de masse 14. Le 2^e groupe positif est précisément celui qui prédomine dans la décharge électrique où l'azote est activé. Je sais que cette attribution de spectres de bandes à des atomes paraît scandaleuse à la plupart des spectroscopistes, mais, dans le cas particulier du 2^e groupe positif de l'azote, elle s'accorde avec la plupart des propriétés de ce spectre.

Elle s'accorde avec l'ordre d'apparition des différents groupes de bandes de l'azote. Elle s'accorde avec les valeurs proposées par Sponer (*loc. cit.*) et Duncan (*Astro. Jour.*, **62**, 145, 1925) pour les potentiels d'excitation du 2^e groupe positif et du groupe négatif, et par R. T. Birge et Sponer pour le potentiel de dissociation de la molécule : ce dernier étant inférieur aux deux autres. J'ai montré qu'elle s'accordait également avec les phénomènes lumineux que l'on observe en dissociant dans la décharge électrique les oxydes NO et NO^2 dont la molécule ne contient qu'un atome d'azote (*loc. cit.*) Enfin cette attribution comble une lacune de la théorie atomique de l'azote actif telle qu'elle est exposée par Sponer.

Si les atomes d'azote jouent le rôle essentiel dans les propriétés de l'azote actif où ils doivent dès lors exister en proportion notable, il devient étrange qu'ils ne manifestent leur présence par aucune émission. La même remarque peut être faite à propos de l'excitation des spectres de bandes de l'azote par chocs électroniques telle qu'elle est décrite par Sponer. Le 2^e groupe et le groupe négatif sont émis à des potentiels supérieurs au potentiel de dissociation. Sponer admet que cette dissociation se produit effectivement. Ainsi donc, dans les conditions où ces deux groupes de bandes sont émis, le gaz soumis au bombardement électronique contient des atomes libres, d'autant plus nombreux que, si l'on en juge par les propriétés de l'azote actif, leur vie moyenne doit être beaucoup plus longue que celle des atomes libres d'hydrogène dans les mêmes conditions. Cependant ces atomes, malgré les chocs d'électrons, d'atomes-ions, de molécules-ions, n'émettent aucun spectre de raies, c'est-à-dire, suivant la conception classique, n'émettent rien. Le spectre de raies, le seul universellement attribué à l'atome d'azote, n'est excité que par des potentiels très élevés. Il apparaît de plus en plus comme un spectre d'étincelle d'ordre supérieur, émis sans doute par un atome ionisé, peut-être plusieurs fois, atome dont la structure est dans tous les cas profondément différente de celle de l'atome neutre normal qui existe dans l'azote actif et est détaché de la molécule par un choc d'énergie minimum. Il me semble plus naturel de permettre à cet atome neutre l'émission d'un spectre de bandes que de lui refuser toute possibilité d'émission.

Dès lors le parallélisme est complet entre les phénomènes observés par Wood sur l'hydrogène et ceux observés par Strutt sur l'azote. Pour les deux gaz la forme atomique, chimiquement active, apparaît dans la décharge électrique dès que la densité des chocs suivis de dissociation est assez grande pour que le spectre de l'atome subsiste à peu près seul dans la décharge.

Je me permets de rappeler ici des expériences qui confirment singulièrement la théorie atomique de l'azote actif et qui semblent avoir été oubliées dans les discutions récentes. Angerer (*Phy. Zeit.*, **22**, 97, 1921) a montré que la neutralisation spontanée de l'azote actif est une réaction bimoléculaire : la formation d'une molécule phosphorescente exige la destruction simultanée de deux molécules actives. Dans l'hypothèse atomique cette loi est évidente ; elle me paraît difficile à concilier, sans de singulières complications, avec la théorie moléculaire de Saha et Sur. M. DUFFIEUX.

Labelling in Public Institutes for the Public.

SIX years' experience of the British public who frequent the Zoological Gardens has given me certain fixed ideas of their requirements, and of their intellectual capacity, which I believe may be of interest to those in charge of museums or any similar public institutions

In 1917 I took over the management of the Insect House, and during the first month, while considering its possibilities and its limitations, I made a particular study of the types of visitors to the gardens, and came to the conclusion that they might be classed under three headings:

(1) The uninformed seeking information, 60 per cent.
(2) The unthinking, 30 per cent.
(3) The instructed and the experts, 10 per cent.

The only possibility of making the Insect House serve the third section was to maintain a supply of rare insects. This is difficult at any time in Great Britain, and during the War was out of the question.

On the other hand, if the activities and any biological facts of interest concerning even common insects could be exhibited in a manner to make them comprehensible to the first and second sections, then the majority of our visitors would be served. For mere exhibits of insects with their names are of no interest to the general public.

It was, however, several months before I learnt how to word explanatory labels, which, of course, are of primary importance. I gave simple lectures in the Insect House 'in the vulgar tongue,' and found that they were listened to with understanding; but when the public were left to obtain information from the labels they would frequently not give themselves the trouble to read them. Pictorial labels were of great assistance, but the wording of the explanatory labels had to be very carefully studied; indeed, after spending many hours in writing labels I have frequently had to re-write them on discovering that the public were not reading them to the end. By many failures I learnt at last that a label to be of service must in the first place be arresting—that is, it must state some interesting matter in the first few words—also that the terms in which facts are conveyed cannot be too simple, and that when any unfamiliar word occurs then the explanation of it must follow immediately. It was a cause of deep satisfaction to me when I discovered members of the working class showing their families or friends round the Insect House *guided by the labels*.

Of recent years much has been done to increase the usefulness of our museums by careful labelling, but it seems to me that much more might be done. When I hear those responsible saying that the public are not sufficiently interested to read labels, I go at once to read the labels myself and draw my own conclusions. I know from experience that the public are ready to be instructed, and actually hunger for instruction; but I think it is not generally recognised how very easily they are discouraged if it means studying what is to them a new language in order to obtain information. L. E. CHEESMAN.

Zoological Society,
Regent's Park, London.

Is the American Slipper-Limpet (*Crepidula fornicata*) an Oyster Pest?

THE shortage of oysters (*O. edulis*) on the European oyster beds has led to the introduction in many places of American oysters, on which the American slipper-limpet (*Crepidula fornicata*) frequently occurs. Oyster-cultivators in various parts of Europe are therefore becoming interested in the possible effects of introducing the slipper-limpet on their beds, so that it has become a matter of economic interest to know the results to date of the introduction of this animal on English oyster-beds since its arrival about 1880 (see Orton, *Proc. Roy. Soc.* B. 91, 1909).

The American slipper-limpet (*Crepidula fornicata*) is undoubtedly regarded as a great pest on the oyster beds in the Thames Estuary at the present time for the following reasons:

(1) It has spread so rapidly and thrived so well in that locality that it is possible to dredge 20 tons a day on some grounds, actually occupied by oysters. In a pit adjacent to—but not actually a part of—the oyster beds the writer took in July 1923 in a few minutes' haul of the dredge 2226 limpets weighing approximately 26 lb. On all grounds it has increased the labour in dredging, while adding only slightly or not at all to the income of the oyster-producer.

(2) The limpets attach themselves in piles or chains on the oysters, which have therefore to be cleaned of limpets as well as barnacles, etc., before sending them away from the beds.

(3) It is impossible to remove Crepidula entirely from the beds, once it is established on the ground, as it has a free-swimming larva—like the oyster—and in addition changes its sex from male to female so that every individual may breed as a female (*loc. cit.*). Moreover, spawning occurs in England from about March to November, and females may spawn more than once in a season.

In favour of Crepidula, it may be said:

(1) That it is not an enemy of the oyster but a competitor for space and food, like sea-squirts, various bivalves, and other plankton-feeding animals.

(2) That where Crepidula occurs in abundance it can be dredged in the normal routine of work, and the shells easily accumulated in great piles and cleaned and bleached to serve as cultch for catching oyster spat. On some beds Crepidula is beginning in this way to pay some of its debts to the oyster-producer.

There can be no doubt, however, that unless Crepidula can be utilised as food—in a small way its shell is utilised in England when crushed with oyster shells as chicken food—it is a great nuisance to the oyster-cultivator. No serious attempt has been made in England to use the slipper-limpet as food, but it is probable that if Crepidula occurred in quantity in France it would be so utilised, and acclaimed as an undoubted benefit.

Photo-electric Polarimetry.

As the use of selenium cells and photo-electric devices is engaging the attention of several workers, a brief account of an application to the polarimeter due to one of our research students—Miss Winifred E. Dickes—may be of interest.

A long series of experiments has led to a simplified arrangement as follows. The apparatus in essentials consists of a spectrometer, for the collimator of which is substituted a polarimeter without eyepiece or half-shadow device, but having a slit over the polariser diaphragm and an electrical photometer behind a slit in the eyepiece of the telescope. An additional eyepiece is placed at right angles to the axis of the telescope for observing the line of the spectrum employed. Half of the field of this eyepiece is fluorescent, for convenience in setting when making determinations in the ultra-violet regions.

The photometer used is a selenium or alkali metal cell, and valve amplification is being tried.

The peculiar novelty of the method is the way in which the observations are taken. A quantitative measure of the light intensity is obtained. Two positions are found, about 90° apart, which give the same current. The mean of the two readings so found gives an accurate value for a minimum or maximum, according to choice, although the minimum as a rule is slightly to be preferred.

The readings 90° apart are taken repeatedly and are averaged in the same way as pointer readings are used in weighing. With a selenium cell, these observations are made at fixed time intervals to allow for the characteristic small secular variation in the current.

Since there is no half-shadow device, the whole of the light can be utilised by the photometer. A magnified image of the polarimeter slit is used for the photometer, in order that a larger (that is, more sensitive) selenium cell may be used.

At the end of 1924, with a rough arrangement, an accuracy had been obtained of 0·01° in the red end of the spectrum and 0·1° in the violet. The work was then interrupted by illness. It is now being resumed, and there is reason to hope that a considerably greater accuracy may be obtained, when a paper will be published.

It is proposed also to investigate two possible extensions, namely, the direct use of the apparatus for absorption measurements, and its adaptation to an automatic or recording polarimeter.

Wordsworth's Interpretation of Nature.

THE introductory lines which appear in the complete collection of Wordsworth's poems crystallise, with such singular fitness, the point of view so ably expressed in the supplement to NATURE of January 16 that I think it is important to direct attention to them:

> If thou indeed derive thy light from Heaven,
> Then, to the measure of that heaven-born light,
> Shine, Poet! in thy place, and be content:
> The stars pre-eminent in magnitude,
> And they that from the zenith dart their beams,
> (Visible though they be to half the earth,
> Though half a sphere be conscious of their brightness)
> Are yet of no diviner origin,
> No purer essence, than the one that burns,
> Like an untended watch-fire, on the ridge
> Of some dark mountain; or than those which seem
> Humbly to hang, like twinkling winter lamps,
> Among the branches of the leafless trees;
> All are the undying offspring of one Sire:
> Then, to the measure of the light vouchsafed,
> Shine, Poet! in thy place, and be content.

The lines in parenthesis surely indicate once more the possibility that Wordsworth might easily have become a man of science, whilst the following lines display, as effectively as anything in the body of his works, that intense spirituality of the poet's vision, the *particular* quality of which is unique among the great English poets. Can there be any lover of Nature but has felt the influence of that star which scintillates above the dark line of the hills, or who does not recognise this imagery to symbolise the whole beauty of a sparkling winter evening—when, may be, one is walking along a country road over the crackling puddles. But there is, further, local colour behind the imagery in question. I can never read the line and a half beginning with "Like an untended watch-fire" without experiencing a vivid sense of the stern background of the Cumberland fells, and of the various moods of that northern climate to which the lakeland hills are so exquisitely attuned. Had Wordsworth been reared in some other part of England equally beautiful, only different, would this have been reflected in the general character, apart from local concrete imagery or topographic detail, of his poetry? To some extent one may, I think, infer this; but in such deep aspects of human geography it is necessary to exercise the utmost caution, for we know little of the influences which affect the human spirit or in what direction they may act.

The Arabic Text of Avicenna's "Mineralia."

THE production of spurious books on alchemy, claiming to be translations from the Arabic, was undoubtedly practised on a large scale in the Middle Ages. An unfortunate result has been that modern scholars are inclined to view with grave suspicion all Latin chemical treatises which pass under the names of Arab authors, and have thus inevitably rejected many books which are genuinely what they profess to be. An interesting case in point is provided by the tract entitled "Mineralia," ascribed to Avicenna and printed in Manget's "Bibliotheca Chemica Curiosa," 1, p. 636, and elsewhere. This was rejected as a forgery by Kopp ("Beiträge zur Geschichte der Chemie," 3, p. 56) and others, though Hoefer ("Histoire de la Chimie," second edition, 1866, 1, p. 345), with a truer insight, regarded it as genuine.

A careful study of the tract convinced me that Hoefer was right, and after a prolonged search I was fortunate enough to discover the Arabic text. The "Mineralia" is, in fact, a close translation of certain sections of a work by Avicenna which is undoubtedly authentic, namely, "Al-Shifā'," manuscripts of which occur in the British Museum and many other libraries. Since Avicenna's views on alchemy (he was a pronounced opponent of those who maintained the possibility of transmutation) exerted a great influence upon contemporary scientific thought, it has been considered desirable to publish the Latin and Arabic texts together with an English translation; this edition is now in course of preparation.

Intrinsic Brightness.

THE intrinsic brightness of sources of light seemed at one time to be a simple matter, namely, 2½ candle-power per square inch for a candle-flame, 200 to 450 for a carbon filament lamp, 1000 for a tungsten vacuum lamp, and 80,000 to 110,000 for an open electric arc. The areas were the simple measured projected areas of the surfaces.

The question arises, however, whether those areas should be taken. The apparent diameter of a modern intensely incandescent filament is greatly increased by irradiation. The fine spiral filament of a gas-filled lamp appears, visually, to be a very thick filament. The bunch of straight up and down filaments of a tungsten vacuum lamp appear, at a little distance, to be a uniform incandescent patch of many times the area of the filaments, and would be indistinguishable from a flat uniformly incandescent surface of the same apparent area. Considerations of comfort, to say nothing of possible injury to the eyes by too great intrinsic brightness, have become important. Opal glass bulbs absorbing an unimportant fraction of the light, are being used for the purpose of increasing the apparent area, and thus reducing the intrinsic brightness. The definition of this quantity appears to be one for physiological or ophthalmic consideration, rather than for simple physical measurement. If the apparent area is to be taken, how is it to be measured? Is it subjective or objective?

Neglected Early Scientific Instruments and Apparatus.

LIKE many other readers of NATURE, I have been greatly interested in the extracts from the early records of the Royal Society and the Philosophical Society at Oxford which have been appearing in its columns. Those recently published illustrate and supplement Mr. R. T. Gunther's "Early Science at Oxford" and bring into relief the pioneer work done in every department of experimental science by graduates of Oxford and Cambridge during the seventeenth century.

As an old curator I know how many unregarded "rarities" are still stowed away, neglected and forgotten, in the cupboards and corners of every local museum throughout the country. I would suggest to those in charge of such museums that they should look through their "lumber" to ascertain whether there are any pieces of scientific apparatus which should again see the light. This was done with brilliant success at the colleges in Oxford in 1919, and the Ashmolean has, in consequence, come into its own again. I feel sure that a more extended search would lead to even greater results, and if the finds were reported to Mr. Gunther he would make a note of them, and it might be possible to gather them together as a loan exhibition.

D'ARCY POWER.

Cirsium eriophorum.

IN NATURE (November 14, p. 711) Mr. Stuart Thompson alludes to the woolly-headed thistle—*Cirsium eriophorum*—being found at Chewton Keynsham, and remarks that it was from specimens gathered there in 1922 that Dr. Petrak named it sub-sp. *britannicum*. As a matter of fact, Dr. Petrak monographed the genus in 1912 ("Bibliotheca Botanica," Heft 78, Stuttgart), which I reviewed in the *Report of the Botanical Society and Exchange Club*, 361, 1913. There Petrak describes seven subspecies, and he chose an inept name (*Cirsium britannicum*), since *eriophorum* is limited to England (Sibbald's Scottish record was erroneous), and there was already *C. britannicum* of Scopoli, but that is *heterophyllum* and therefore invalid. So far from the subspecies being due to a Somerset specimen, Petrak's details of his drawing are made from a Huntingdonshire plant.

Oxford.

Eclipse Observations in Sumatra, January 14, 1926.

By Lieut.-Col. F. J. M. STRATTON.

EXCEPT for an Italian expedition to the east coast of Africa, all the astronomical expeditions to observe the eclipse of January 14 stationed themselves in Sumatra. A Dutch expedition under Dr. van der Bilt, with Prof. Pannekoek, Dr. Moll, and Dr. Mynnaert, was at Talangbetoetoe on the central line, near Palembang. Its programme was mainly spectroscopic and spectrophotometric—the distribution of gases in the layers of the corona being a special problem attacked. Most unfortunately, this station was clouded out completely.

FIG. 1.—Mr. C. R. Davidson, with the 10-foot camera and 40-foot objective prism camera.

A party from the American Naval Observatory, basing the choice of station on experience from the 1901 eclipse in Sumatra, was established at Kepahiang, a station in a high valley amongst the mountains which form the backbone of Sumatra. This party consisted of Capt. Littell, Dr. Peters, Dr. Kellars, Lieut. Ransford of the U.S. Naval Observatory, with Dr. Anderson, of the Mount Wilson Observatory. The party was assisted by a detachment of sailors from the U.S. Navy. A telescope of 70 ft. focal length was erected for direct photographs of the corona, and the programme included grating spectrograms with a moving plate of the flash and of the corona. Unfortunately, the sky at Kepahiang only cleared for the last seventy seconds of totality, but a curtailed programme was carried out successfully. The sky had been clear two minutes before totality, but a passing cloud robbed the observers of the first two minutes of totality.

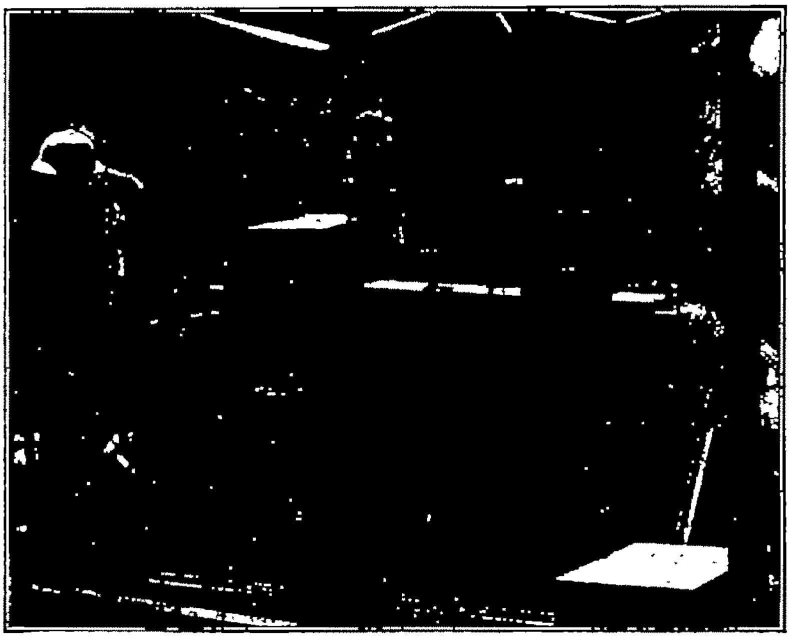

FIG. 2.—Mr. Z. A. Merfield, with spectrophotometric equipment.

At Benkulen, on the south-west coast, three or more expeditions placed themselves. The German expedition under Dr. Freundlich consisted of Prof. Keinle, Dr. von Klüber, and Dr. Mollet. Prof. Voûte, of the Lembang Observatory in Java, Mr. Kerkhoven, and Dr. Knol also joined this party. The programme was mainly the Einstein problem with some spectroscopic work as well. The equatorial telescope taken to Christmas Island in 1922 was used again, and in addition two horizontal telescopes, fed by the same cœlostat and giving simultaneously the sun's field and a second star field, were in use. The sky near the sun was clear throughout totality save for slight cirrus cloud passing over the sun, but the complete programme, including all the comparison plates, was carried out, and it is hoped that the required stars figure on the Einstein plates, and that Prof. Freundlich's continued ill luck at eclipses has ended happily. Attached to this expedition, but available for the other parties at Benkulen, was a field workshop under Mr. Verhoeff.

The American expedition from Swarthmore College was also at Benkulen. Prof. Miller was the leader of the party, and his consistent good luck at eclipses held once more. With him was Prof. H. D. Curtis from

Allegheny, Dr. Marriott, Mr. Dominick, Mr Wilson Powell, Mr. A. Rubel, and Dr. D. B. McLaughlin. Their programme included the Einstein problem, photographs of the corona with a 63 ft. tower telescope, interferometer measurements of the wave-length of the green coronal line, objective grating spectrograms in the infra-red, and colour photographs. The early development of their plates showed general success over the whole programme. Another expedition, camped in the same field, came from Harvard under Prof. Stetson, with whom were Dr. Coblentz, Mr. Weld Arnold, and Mr. W. A. Spurr. Their programme was mainly photometric, and was partially spoiled by the slight haze present in the sky. Capt. Harris, of the U.S Signal Corps, also joined the American expedition with a cinema camera with which he hoped that he had been successful in photographing the elusive shadow bands as well as the whole eclipse.

Fig 3.—Prof. Freundlich's Einstein camera.

The expedition sent out by the Joint Permanent Eclipse Committee of the Royal Society and the Royal Astronomical Society consisted of Mr. C. R. Davidson and Lieut.-Col. F. J. M. Stratton. There joined the party as volunteers Dr. F. W. Aston, Col. J. Waley Cohen, Mr. E. G. Barton, and Major R. G. R. Davies. The expedition was very appropriately and most happily given accommodation in the old British fort—Fort Marlborough—built more than two hundred years ago and now the barracks of the native police. At this station the sun was absolutely clear during the whole of totality, though there was thin cirrus cloud in the immediate neighbourhood of the sun—cloud which passed over the sun during totality for the American and German expeditions less than half a mile away. The main programme was spectroscopic, both the corona and the flash being examined in the extreme infra-red and ultra-violet. Objective prism spectrograms were also obtained of the flash and of the corona in the photographic and visual regions.

Fig. 4.—Prof. J. A. Miller's 63-foot tower telescope with the Einstein telescope in foreground.

At the time of writing, only part of the plates have been developed, but they are sufficient to show that the expedition has been generally successful in its programme. Mr. Barton's programme was mainly photometric, his intention being to measure the total intensity of light from first to last contact; unfortunately, just at the commencement of totality the recording tape broke through a flaw in the paper, an accident which robbed his work of its most important phase.

The British expedition was joined by Mr. Z. A. Merfield, of the University of Melbourne, who was equipped with a moving plate grating spectrograph, a battery of eight cameras with different colour filters to study variation in the corona, and a moving plate colour filter photometer. The instruments were mounted on a polar axis and were all set up and adjusted in time, though owing to a series of accidents they did not arrive until eight days before the eclipse. Here again, general success is indicated by the plates so far developed, and a useful contribution promised to the question of the distribution of solar vapours in the higher chromosphere. Mr. Bridges, of the *Melbourne Herald*, was also attached to the British party as a volunteer, and a cinema camera of his was used with one of Mr. Merfield's parabolic gratings to get a timed series of photographs of the spectrum at the second and third contact. This instrument was worked by Capt. Akkersdyk, who was in command at the Fort and who helped the British expedition by every means that lay in his power. The photographs illustrating this article were taken by Mr. Bridges.

The choice of Benkulen as the site for most of the expeditions was based upon careful observations on cloudiness at eclipse time in previous years. These were made under the direction of Dr. Braak of Lembang, and they proved a useful guide to the visiting astronomers. It should be added that the facilities at Benkulen, and the friendly help given freely on every side, showed how luckily the choice of a site had been made.

The season—the rainy season—was not at all promising, and for the month preceding the eclipse the numbers of fine and cloudy days were about equal. The day of the eclipse itself was cloudy most of the morning, but the sun cleared up for first contact. Thin cloud gathered between first and second contact, but cleared away shortly before totality. Five minutes after the end of totality, the sun was in cloud for the British station.

The corona was intermediate in type, resembling that of the 1900 eclipse in India. There were several very striking prominences on the limb, and the black moon, ringed with bright red prominences and surrounded by the pearl grey corona with its long irregular rays, made a wonderful picture, well worth travelling thousands of miles to see.

Space, Time, and the Universe.[1]

By J. H. Jeans, Sec. R.S.

SOME of us may remember the story of the children who played truant in order to explore the regions where the rainbow ends. After travelling all day, up hill and down dale, they had to admit failure of the most thoroughgoing kind—the rainbow was, to all appearances, no nearer than when they started. Really scientific children might have thought of estimating their rate of approach to the rainbow by measuring the angle it subtended. If they had measured it in the morning it would have been 42° 23′; it would have been 42° 23′ at noon, and again at night it would still be precisely 42° 23′. If they had done this they must have felt that they were the victims of extreme bad luck, for they had clearly seen the rainbow in front of the nearest hill when they started out; could there be some sort of conspiracy on the part of rainbows, hills, and indeed the whole scheme of Nature, to prevent their getting close up to that rainbow?

In the year 1905 the world of physicists was engaged in a pastime which was, in many respects, very similar to that of chasing rainbows. They believed light to travel through an ether with a speed of 300,000 km. a second. If the solar system were travelling through this ether at a speed of, say, 1000 km. a second, it would partially overtake light travelling in the same direction, so that this light ought to appear to travel at only 299,000 km. a second. On the other hand, light travelling in the opposite direction ought to appear to travel with a velocity of 301,000 km. a second. This suggested an obvious means of discovering both the speed and direction of the earth's voyage through the ether—indeed, it was every bit as obvious as the children's plan for exploring the foot of the rainbow. Experiments were designed to utilise this principle and were tried time after time, not in one form only but in many. Time after time experiment gave the answer that the velocity of the earth through the ether was zero, or at least, to put it in another form, which was at that time thought to mean precisely the same thing, the velocity of light relative to the earth was the same in all directions. No doubt it was conceivable that on the occasion of the first experiment the earth really might have happened to be at rest in the ether, but it was quite inconceivable that this should be the case every time; indeed, the earth's orbital motion alone required a variation of some 30 km. a second, and all the experiments were capable of detecting far smaller variations than this.

At first glance it looked as though the earth must be carrying its own private ether about with it, and I suppose this view would have prevailed had it not been for the astronomers, who were ready with an aberration-constant which at once, and, I think, irrevocably, dismissed the possibility of an ether being dragged about with us. Incidentally, this episode provides an often overlooked instance of the services of astronomy to the other sciences and to the growth of knowledge in general. The physicists on Jupiter may still believe that a luminiferous ether exists which follows Jupiter about wherever it goes; the reason is that there are no astronomers on Jupiter to put them right, their permanent blanket of clouds not encouraging this profession.

I forget the end of the story of the rainbow quest, but am prepared to provide an entirely unauthoritative ending. After the children had got completely tired in their bodies and still more completely bewildered in their wits, they rested for a long time, until they encountered a magician. He was not in the least the conventional magician, ponderous of speech and with a long white beard; indeed, he was a young man of twenty-seven, extraordinarily simple and unassuming in all that he said. What he said in brief was this: "I can tell you what is the matter. You have started to chase the rainbow on the supposition that it is a material arch; in actual fact it is all in your own eyes. Gretchen sees one rainbow and Hans sees a quite different one. But if Hans walks up to where Gretchen is standing, he simply changes his rainbow for hers; you don't get any nearer to a rainbow by walking this distance because there isn't really anything for you to get any nearer to. The angle you have been measuring must always stay at 42° 23′; it is fixed there by the unalterable laws of Nature, and children cannot alter these by walking about." As the children were tired, and the young magician had perhaps expressed himself in rather unfamiliar ways, they did not at first quite understand what he meant. But then another magician, whose name was Minkowski, came along, and he made it all seem much simpler; he said it was quite true that each child carried its own rainbow about with it, but that behind the subjective vision of the rainbow was an objective reality consisting of a shower of raindrops. These raindrops were the same for everybody, but out of the whole lot each person's eye selected, or rather the sunshine selected for each person's eye, a small group of drops which appeared to him to form a bright arch. If all space were filled with children standing in different spots, then the aggregate of all the raindrops seen in all the children's eyes would constitute the reality behind the whole phenomenon, a shower of rain. When the second magician put things in this way the children began to understand; they saw that the first magician, whose name was Einstein, had been right.

---

[1] Presidential address delivered before the Royal Astronomical Society on February 12, on the award of the gold medal of the Society to Prof. Albert Einstein for his researches on relativity and the theory of gravitation.

I doubt if the Royal Astronomical Society has ever had its medallist introduced to it in so disrespectful a way before, but my little parable may remind you of the way in which our present medallist made his entry into the scientific world, and also of the way in which the scientific world made their entry into the changed universe in which science moves to-day. Time and space, as separate entities, the time and space we wrote about and thought about previous to 1905, have gone, or, as Minkowski puts it, have become shadows, while only the product of the two remains as the framework in which all material phenomena take place. Time and space separately may mean something to us subjectively, but Nature knows nothing of them until they have been multiplied together into a four-dimensional space-time continuum; it is in this that she has set her laws. If I have seemed to treat Einstein's great early work too lightly, I would plead, first, that it has already suffered enough serious exposition, and, secondly, that only really great work permits of being treated lightly, and that it is well to take a chance when it offers itself. But let not the lightness of treatment be thought to imply lightness of esteem for the work. By his single 1905 paper, Einstein started a revolution in scientific thought to which as yet we can see no end, to which, indeed, we can scarcely yet imagine any end. Had he written only that one paper, his position as one of the great figures of science would, in my opinion, have been secure. He would, perhaps, not have been awarded the gold medal of our Society, but that would be because he had not yet become an astronomer.

If the magicians had given the right explanation of the rainbow, then everything the children saw in the rainbow ought to admit of explanation in terms of the ultimate reality provided by the shower of rain. Obviously there would have been something radically wrong if Gretchen had seen a circular rainbow while Hans, standing by her side, had seen a square one; something wrong, too, if Gretchen had said that the colours ran from red to blue as you passed inwards, while Hans said they ran from blue to red. In the same way, if Einstein and Minkowski were right about time and space, there must have been something radically wrong when Isaac Newton had said that every particle in the universe attracted every other particle with a force that varied as the inverse square of the distance, and again when he had said that the path of a planet about the sun was an endlessly repeated ellipse. When the last of these statements, for example, is expressed in terms of the four-dimensional framework which Einstein and Minkowski regarded as the ultimate objective reality, it is found to make sheer nonsense, to be inconsistent with itself. Viewed in that framework, an endlessly repeated ellipse becomes a sort of helical curve, a spiral staircase climbing up into eternity, the projection of which on one particular cross-section is the single ellipse in question. View it at any angle you like and it is still a helical curve, but project it on some other cross-section and you will find that the radius vector relative to the sun no longer describes an endlessly repeated ellipse. In brief, the Newtonian law of gravitation could not be true because it could not be expressed in terms of the ultimate four-dimensional reality in such a way as to be true for more than one person at a time.

When Einstein had this brought to his notice he at once became an astronomer. His task, rather a heavy one for the first piece of work of a young apprentice to astronomy, was to find out what was the matter with Newton's law of gravitation and to put it right. Of course, in a sense, there was not very much wrong: Halley's comet had come back when it was expected, and Jupiter's satellites could be seen every night exactly as the pictures in the "Nautical Almanac" predicted that they ought to be seen if Newton had been right, and all the planets seemed actually to be describing endlessly repeated ellipses except that Mercury wandered very, very slightly from its proper place. Yet, in another sense, there must be everything wrong with a law that did not fit properly into the four-dimensional reality, or at least there was as much wrong as the difference between truth and error, which the true man of science regards as the biggest magnitude with which he ever has to deal. And, just as Kepler, starting from the established error of 8′ in the observed position of Mars had set out "to construct a new theory that will explain the motions of all the planets," so Einstein set to work to construct a new theory which was incidentally to explain the motion of the planets but was destined also to change our whole interpretation of the fundamental significance of these motions.

Every astronomer is familiar with this part of Einstein's work. By 1915 he had found the modification needed in Newton's view of gravitation, and had shown that the orbit of a planet, instead of being the impossible endlessly repeated ellipse, was an ellipse which kept slowly turning round in its own plane. He had also found that the theoretically predicted rate of turning for Mercury was exactly the 43″ a century by which Leverrier had found that the planet's perihelion advanced over and beyond the advance caused by the pull of the other planets. He announced two further physical consequences of his theory. Rays of light passing through a gravitational field ought to be bent by a calculable amount, 0·745″ for light which has just grazed the sun's limb; and spectral lines emanating from atoms in a gravitational field ought to be displaced towards the red, the displacement of lines from the solar photosphere being that corresponding to a velocity of 0·634 km. a second, or, say, 0·008 Å.U. at the cyanogen band, λ3883. Newton had queried in his "Optics" whether rays of light would bend in obedience to gravitational force, but Einstein was the first since Newton to make any definite physical predictions arising out of a theory of gravitation.

Our two British expeditions put the first of these predictions to the test at the 1919 eclipse, and, as we know, brought back the news that the prediction was amply verified. The testing of the second prediction was a more difficult matter, not so much because the small displacement of 0·008 Å.U. was difficult to measure, as because it was masked by bigger displacements of unknown amount. Even to-day the problem can scarcely be said to be solved with absolute finality so far as solar light is concerned, although probably Evershed, St. John, and others have done all that it is possible to do. But the prediction which it was found almost impossible to test by the light of our sun has been tested by the light of one of the faintest of stars. Sirius has, as companion, a smaller and far fainter star which describes an orbit round it. Its effect on the motion of Sirius shows its mass to be 0·85 times that of the sun, and its distance is for all practical purposes the same as that of Sirius. The amount of light it emits is so small that Seares had calculated its radius to be only about 20,000 km. or one thirty-fifth of the radius of our sun. Now Einstein's theory predicts a shift proportional to M/r, so that whereas the predicted shift in the solar spectrum corresponds to a velocity of only 0·634 km. a second, the light from the companion to Sirius ought to show a shift corresponding to a velocity of 20 km. a second, something like a third of an angstrom. Here then was a shift the magnitude of which was suitable for measurement. The measurement was undertaken at Mount Wilson, and the observed shift was found to agree almost exactly with that predicted by theory. This experiment not only established the validity of Einstein's theory of the gravitational displacement of spectral lines, but also showed its usefulness as an instrument to be utilised by the practical astronomer in his everyday work.

The ultimate importance of Einstein's work was not, however, that it gave astronomers new tools for the measurement of stellar diameters, or for the prediction of the position of Mercury; it was not even that it gave the true law of gravitation; it was that it gave a new conception of the meaning of gravitation and of gravitational force. Strictly speaking, Einstein did not amend Newton's law of force; he abolished it. He put something else of a quite different nature in its place, something which was consistent with itself when looked at in the four-dimensional continuum and agreed with the observed facts of Nature, including the then untested bending and reddening of light. At first he had tried to amend Newton's law to fit the continuum, but he soon found it was a case of amending the continuum so as to fit Newton's law. Or rather, since a perfect fit was impossible, this being the cause of all the trouble, he amended the continuum so as to fit Newton's law in the only region where it could fit, namely, at infinity, and then found that the misfit for nearer distances gave just the needed 43″ a century for Mercury's orbit. Just as completely as, some three centuries earlier, the kinematical explanation of cycles and epicycles had crumbled to nothing in the hands of Kepler and Newton, so now the dynamical explanation of a gravitational force crumbled in the hands of Einstein. The story of this part of Einstein's work has been so often told and is so familiar to all astronomers that you will scarcely wish to linger over it. It opened up a path into entirely new scientific territory along which Weyl and others have advanced, attempting, so far as can at present be seen with success, to extend Einstein's fundamental conceptions so as to explain the "forces" of electromagnetism in terms of a still further generalisation of the geometry of the continuum. If they have succeeded, the mechanism of the whole universe is transformed; dynamics disappears from science and the laws of Nature are those of geometry alone.

We need scarcely spend time over the threadbare and rather meaningless question of whether Einstein has performed the feat of "abolishing the ether." So much depends on what we mean by "ether." As soon as the term is defined, the question as to whether or not that particular ether exists almost answers itself—generally in the negative. The luminiferous ether of Kelvin, Maxwell, and Faraday, largely as the result of Einstein's new outlook on the universe, may be described as dead; it is no longer a serious scientific hypothesis, but merely an item in the unscientific jargon of popular expositions of "wireless."

Let us take a glimpse at the new universe into which Einstein's work has led us. Until the seventeenth century the majority of men believed that terrestrial life was the prime reason for the existence of the myriads of stars that lighted the firmament; they had indeed been created just a few days before man so as to be ready to minister to his pleasure on his arrival. In the twentieth century the majority of men believe that there is a sort of flow of time which is regulated by our consciousness. We live now in the year 1926, and therefore speak of 1925 as dead and past; 1927 is not yet born, but will spring into life for us just as soon as we need it, which will be when we reach the end of 1926. So the traveller journeying west through Devon might suppose that Somerset had fallen out of existence at the moment he left it, and that Cornwall was waiting only for his arrival to come into existence. Foolish, perhaps, when expressed in terms of space, and yet our everyday belief in respect of time.

Einstein's theory eliminates the supposed essential difference between space and time; what is one man's space is another man's time. Not only so, but what is the past in time for one man is the future for another man. According to the view thrust upon us by the theory of relativity, the space-time landscape does not spring into life in front of us and die behind us; it is unalterably there. Existence becomes a picture rather than a drama, and the year 1927 has the same sort of existence as the county of Cornwall. Probably no one would regard this as a final statement of the matter; it goes as far as the theory of relativity carries us, but the theory of relativity is concerned only with inanimate Nature; it takes no cognisance of life or consciousness. It is for us to go further if we can.

Does the theory, however, leave room for us to go further? Does it leave room for life and consciousness, and for the attributes, such as free-will, which we attach to them?

The materialistic philosophy of a generation ago used to insist that the picture which science then presented of the universe left no room for such things. That picture has no doubt been torn to shreds, but what about the new picture? Does this look with any more favour on our instinctive belief that we can guide our actions and make the universe in some small degree different by our presence? Or are we mere passive spectators, carried—in a train the speed of which we cannot regulate and the course of which we cannot alter by an inch—out of a Devon with which we can do nothing except gaze at it through a window, into a Cornwall which is already in existence and has been unalterably created by other hands than ours? To this last question the answer of the theory of relativity would seem to be in the affirmative, but relativity is not the whole of natural science; it is not even the whole of Einstein's work. His contributions to science fall into two columns which, unhappily, are parallel and show no signs of meeting. The first column contains his contributions to the theory of relativity, the red-letter years being 1905 and 1915; the second column contains his contributions to the theory of quanta, the red-letter years being 1905 and 1916. It is not yet altogether clear which of these columns will figure most prominently in the history of present-day science when this is finally written in its proper perspective. But it already seems possible that the second column of Einstein's work may contain the needed antidote to the determinism and automatism to which the first column, if it stood by itself, would seem to condemn us.

This room contains, let us say, a thousand atoms of uranium. The chances are that after five million years only 999 of these will be left, the other one having been transformed into an atom of lead, eight atoms of helium and about 10^{-27} grams of radiation or heat. One of the thousand atoms is fated to be transformed in this way, but what determines which particular atom it is to be? Are we tempted to conjecture that it will be that one that gets most knocked about in the interval, or that gets into the hottest places, or what not? If so, we are wrong; for if blows or heat could disintegrate the one atom they could also disintegrate the other 999, and yet every physicist is firmly convinced that no possible treatment can retard or expedite the disintegration of the uranium atoms in the least degree. Once every five million years fate knocks at the door of one atom and it breaks up. Why fate chooses this interval, why she selects one particular atom rather than its fellow, we simply do not know; we seem to be beyond the domain of what have heretofore been called natural laws.

Now let us think of a more familiar, although more complicated, phenomenon. The hot filament of an electric light bulb receives energy from a dynamo and discharges it as radiation. Inside that filament millions of atoms are jumping up and down between different energy levels, and Einstein has investigated what may be called the statistics of their jumping about. Most of the knocks now are just those of ordinary radiation. The temperature radiation of the filament knocks some atoms up and some down; double the stream of radiation and the atoms will be knocked up and down twice as frequently. But this is not the whole story; if it were, the emission of light from the filament would not be what exact experiment shows it to be. Einstein finds that to explain the observed stream of radiation from the filament, fate must be invoked here also. Some atoms are knocked down from the high energy level to the lower because the stream of radiation pushes them down, but others stumble down by processes analogous to those by which the uranium atom disintegrates. They stumble, if you like, of their own clumsiness, or, if you like, because fate beckons them down. Put it anyhow you like, and you will almost certainly be wrong; Einstein has shown that it happens, and beyond this we know nothing.

It is, however, clear that we may be in the presence of something here which is quite beyond the inflexible cause and effect of the older mechanics, and possibly equally beyond the precreated tangle of events of the theory of relativity. A single instance will perhaps suggest how far beyond. The lines of the hydrogen spectrum result from the falling down of the atoms of hydrogen from one energy level to another, and in the determination of the wave-lengths represented by these lines, the future of the atom enters as an equal partner with the past, although, as we have seen, the future of an individual atom can no longer be regarded as a consequence of its past in the sense in which an effect is the consequence of the cause. We are here in unfamiliar regions of thought where our minds get frozen and refuse to operate. But one thing at least seems possible. It seems as though the deadly inevitability of cause and effect has ended, and we are in the presence of new possibilities of freedom which as yet we do not understand. Einstein's work on relativity changed the universe from a drama into a picture. It seems possible, as Weyl first suggested, that his work on quanta may have provided the clue which is destined to change it back again into a drama—no longer a drama in which all the parts have been written and the gestures prearranged before the curtain went up, but a drama in which all the actors choose their actions as the play proceeds—in fact, not a staged drama, but life.

No doubt the great mass of the universe must always follow a predestined path; nothing but predetermined forces can bind the cluster of the Pleiades or loose the bands of Orion or guide the Bear with its train, but there is now, for the first time since Newton, room in the universe for something besides predestined forces. No doubt this is only a possibility, only a conjecture if you like. We do not understand quantum phenomena well enough to go beyond conjectures. Perhaps a hope is dawning that some quite recent investigations of an abstruse mathematical nature are going to provide an answer to the puzzle, but if so it seems probable that the answer will not be in terms of ordinary time and space, and so will come from outside the regions surveyed by the theory of relativity. In any event it seems that there must be room for much in the universe about which relativity knows nothing. Perhaps the two columns of Einstein's work, which never clash because they never meet, provide a true symbolical picture of the universe which he has done so much towards elucidating.

Obituary.

DR. W. BATESON, F.R.S.

BORN in 1861, William Bateson was educated at Rugby School and at St. John's College, Cambridge, of which college his father was Master. He obtained first-class honours in both parts of the Natural Sciences Tripos, and took his degree in 1882. It was at the time when the genius of Francis Balfour had given a great impulse to the study of comparative embryology, and it was natural that Bateson's first efforts in research should be along such lines. As a subject for investigation he chose Balanoglossus, the position of which in the phylogenetic scheme was then one of uncertainty. To obtain material he visited America in 1883, and again in 1884. His results, which appeared in a striking series of papers in the *Quarterly Journal of Microscopical Science*, definitely fixed the position of Balanoglossus, and are now incorporated into every text-book of zoology. In 1885 he was elected a fellow of his college.

Not the least important outcome of Bateson's visits to America was the meeting with W. K. Brooks, who undoubtedly influenced his thoughts towards the direction they were now to take. The age-old problem of the nature of species gripped and held him for the rest of his life. Though fully appreciative of the value of morphological inquiry, he came to distrust the phylogenetic-speculations that were based upon it, involving as they did the assumption of hypothetical variations to fit the case. He demanded reality, and set to work to search it out. Holding that the facts of variation must be the test of phylogenetic possibility, he started to collect records of such variations as actually exist. The literature was searched, museums were visited at home and abroad, collections were made in the field, and it was at this period that as Balfour Student of the University of Cambridge he made a journey to the western parts of Central Asia and Siberia. The immediate outcome was the "Materials for the Study of Variation" (1894), a book which marked an era in the development of biological thought.

At that time it was generally held by professed authorities that variation was of the nature of a continuous process, and that the discontinuity of species was brought about by the operation of natural selection on such material. Logically this amounted to a denial of the existence of species as recognised by the systematist. Bateson reaffirmed the reality of species, emphasising the discontinuity between them, and pointed out that such discontinuity was paralleled by discontinuity in variation. As to the existence of this phenomenon the collected evidence left no doubt, and it was reasonable to suppose that the observed discontinuity in species was based upon discontinuity in variation.

To the naturalist the book was at once a warning and a call—a warning that the quest upon which he was engaged might be based upon illusion: a call to the study of variation, which at that juncture seemed to offer the fairest hope of progress in connexion with the species problem. Looking back, it seems surprising that the forceful reasoning of this remarkable book should not have made immediate converts. Yet so it was, and though the cause lay partly in mental inertia and indifference, it lay partly also in the rise of the biometrical school of evolutionists. Basing their methods upon the conception of variation as a continuous process, it was not unnatural that they should show a lack of sympathy with the evidence for discontinuity and all that it implied. Controversy became keen, and Bateson was more than once called upon to defend the position he had taken up. The ability with which he conducted his case, and the freshness of his outlook, began to attract to him the allegiance of some of the younger men, who felt that a new force had entered into their studies.

Meanwhile Bateson had started on another line. Satisfied as to the existence of discontinuity in variation, he felt that the next step was to discover how such varieties behave on crossing. He carried out an elaborate series of breeding experiments in Lepidoptera, especially with the *bryoniæ* form of *Pieris napi*, and certain geographical races of *Pararge egeria*. The results were difficult to interpret and he came to the conclusion that, if headway was to be made, material must be chosen in which the problem was reduced to its simplest form. In collaboration with Miss E. R. Saunders, a series of experiments was begun with plants where a sharp discontinuous variation existed together with the normal form, and a year later experiments planned on similar lines were undertaken with poultry. The aims underlying this work, and the hopes entertained of it, are set out in an address to the Hybrid Conference held in London during July 1899. Noteworthy is the announcement that discontinuity in heredity had already been detected, as also is the stress laid upon the necessity of examining the outcome of a cross *statistically*, and of marshalling the offspring in respect of each differentiating character separately. It was precisely this method of analysis that led to Mendel's success, and even if his famous paper had remained unknown, it is likely that the world would not have had long to wait for that guiding principle which lifted the study of heredity into its place among the exact sciences. Be that as it may, the discovery of Mendel's work in 1900 found Bateson well prepared. He intuitively recognised its high quality, and at once seized upon the essential truth of the purity of the gametes in respect of definite characters. In the following year he communicated to the Evolution Committee of the Royal Society an illuminating report, summing up the evidence and indicating the bearing of Mendel's discovery upon cognate lines of work. It was a report that opened men's eyes to the greatness of the achievement, and it exerted a strong influence in inducing others to pursue such investigations.

In Great Britain, however, there was opposition from one quarter, and that an influential one. The biometricians had already given evidence of hostility to the idea of discontinuity in variations. Exponents and upholders of what was known as the law of ancestral heredity, they could not but realise that the acceptance of the doctrine of gametic purity must shatter the very foundations upon which they were striving to build. With the revelation of discontinuity in heredity, it was open to them either to throw over the law of ancestral heredity, or to combat the new doctrine in whatever way they could. The latter course was chosen, and in *Biometrika* for January 1902 appeared a paper by Weldon minimising the importance of Mendel's discovery, and stating that neglect of ancestry was a fundamental mistake vitiating all work based on Mendel's methods. A challenge of this sort coming from such a quarter could not be overlooked. A great cause was at stake, and some few months later appeared "Mendel's Principles of Heredity: a Defence," a book in which Bateson gave free scope to his great powers of analytical criticism and to his remarkable gifts for controversy. The issue was joined, and Mendel was at any rate assured of his hearing. Two years later came the great clash at the meeting of the British Association in Cambridge. Bateson, as president of the Section of Zoology, delivered a stirring address vindicating the methods of Mendelian research, and challenging the conceptions of the biometrical school. The heated debate which succeeded it was keenly followed by a crowded audience, and at the end of it there was no mistaking the feeling that the exponents of Mendel had made good.

Meanwhile, Bateson had thrown himself wholeheartedly into the exploration of the fresh field that had been opened up, and the next few years were fruitful in discovery. To this period belong the formulation of the presence and absence theory, the solution of the old problem of reversion on crossing, and the demonstration of the nature of sex-linked inheritance. Another discovery of the first importance was that of linkage of characters. Originally detected in the sweet pea, the phenomenon was first fully explored in this material, and eventually fitted into an orderly scheme. Its later development in the hands of the American school of geneticists, and its translation into terms of the chromosomes, are now part of the history of science.

Bateson stood, however, for more than discovery. The new spirit that he breathed into the work, and the freshness of his outlook, were an irresistible attraction to many younger workers who desired nothing better than to cast in their lot with his. He became the founder and inspirer of a Cambridge school, and in 1908 the University recognised his peculiar position by creating for him the chair of biology. In the following year appeared "Mendel's Principles of Heredity," a critical survey of the state of genetical knowledge. Nevertheless, immersed as he was in breeding work, the problem of species was always with him; and when he was invited to deliver the Silliman lectures in 1907 he elected to give, not an exposition of Mendelian heredity, but a fresh consideration to the problems of variation and of species. The lectures eventually took permanent form in the "Problems of Genetics" which appeared in 1913. Perhaps the most valuable part of the book is the illuminating discussion on variation in connexion with locality and climate, though at the time of its publication the chapters which attracted most attention were those dealing with adaptation and the effect of changed conditions on the organism. About that time there had appeared several plausible accounts of the induction of a variation through a change of conditions, and of its subsequent inheritance. The searching criticism to which Bateson subjected the evidence was of the greatest service in checking any easy acquiescence on the part of biologists and others less familiar with such branches of inquiry.

The Cambridge period came to an end in 1910 on the acceptance of the directorship of the newly founded John Innes Horticultural Institution at Merton. It was a great opportunity, and Bateson made magnificent use of it. When he went there was nothing; in a few years there grew up a splendidly equipped station, and, of far greater moment, an enthusiastic and devoted band of workers. Here, too, his position gave him better facilities for promoting that co-operation between the practical breeder and the man of science upon which he had so often insisted. He made the breeder feel that his problems were also the problems of science, and out of his sympathy begat trust. Of his own inquiries at this period, and of those directly inspired by him, the key-note was segregation, its nature and the time of its occurrence. To this impulse we owe the striking series of investigations on variegation, bud sports, and root-cuttings, and on the phenomenon of anisogeny, accounts of which appeared from time to time in the *Journal of Genetics*; and it is in the fitness of things that his matured judgment on these phenomena should have appeared in that journal only a few days before his death.

Such in brief outline was Bateson's record of scientific achievement. Fearless in criticism and generous in appreciation, he stood above all for that spirit of freedom in inquiry through which alone the world may progress to better things. In that noble passage which concludes the preface to his greatest book, he has recorded for us in unforgettable words his lofty conception of the calling of the naturalist. By no man has this been more finely set forth: by none has it been more truly lived.

PROF. J. F. GEMMILL, F.R.S.

JAMES FAIRLIE GEMMILL was born at Mauchline in Ayrshire, and went from the village school and Kilmarnock Academy to the University of Glasgow. After a long and distinguished course in arts (honours classics, 1890), medicine (M.D. honours, 1900), and science (D.Sc. 1910), a period in Germany, a taste of medical work, and some travel, he became a research fellow in embryology in the University of Glasgow and a teacher of zoology to training college students. He was greatly influenced by the anatomical teaching and evolutionary thinking of Prof. John Cleland, for whom he had a very strong affection.

It was early in the Glasgow period that Gemmill became keenly interested in the Millport Biological Station, to which for many years, with extraordinary persistence, he devoted much of his time, not only contributing to the output of research, but also encouraging others to join in, and otherwise helping in the educational side of the Station's work. Until he was called to the Dundee chair of Zoology in 1919, Gemmill was a disinterested and loyal friend of the Millport institution, which after many ups and downs of youth has at length attained to a vigorous maturity. Others have greatly aided, but Gemmill's patient fostering in early days should never be forgotten.

Gemmill had wide zoological interests—anatomical, faunistic, ecological, and embryological; but the last was strongest. His researches on the development of echinoderms will form his chief zoological monument; they are masterly in their precision of observation and shrewdness of judgment. But one remembers also his embryological studies among cœlenterates, and his big memoir on the teratology of fishes (1912). When he went to Dundee, he told us that he had passed a self-denying ordinance, and was going to devote himself for some years to a study of practically important farm-pests; and so he became immersed with his usual enthusiasm in the unravelling of the life-history of a species of Bibio, and of some other parasites, such as an elusive tapeworm that is common in lambs. He had a great interest in mechanical devices, of which his little marine aquarium was the simplest—a study aquarium in which he kept sea-animals flourishing in the heart of Glasgow, and even discovered new Clyde species from there. We hope his technical ingenuities will not be lost sight of.

Prof. Gemmill was very happy in his Dundee years. He enjoyed the concentration of his academic work and the opportunities it gave him for diffusing and fostering an interest in biology through the Natural History Society, and the like. His election to the Royal Society came as another encouragement. He found great delight in furnishing an interesting old house, and he was helped at every turn by his niece, to whom he was devoted. He was never the same after her sudden death in 1924.

We should like to be allowed to pay a more personal tribute of affection to one whom we have been proud to call friend for many a year. Gemmill was a singularly lovable man, quiet and gentle, but very strong in grip and firm in judgment. Even for Scotland he was unusually thoughtful, always pondering; even for a scientific investigator, he was unusually cautious. Thus his clear-cut judgments, when the evidence seemed to him sufficient to warrant a conclusion, were always worth waiting for. Of judgments on persons we never heard him give one, though he had his share of fighting, and when an outspoken personal condemnation was uttered in his hearing, his grave face would become graver still and sad. Yet he was no 'Heaven and Hell Amalgamation Man'; on the contrary, a very clear-headed discriminator of persons.

What a fine companion Gemmill was, radiating cheerfulness, enlivening on a long walk, heartening when the dredge was coming up, magnanimous on the golf course, but always in his own peculiarly restful quiet way. Never of the strongest, he was very wiry, with great power of physical endurance, and on his holiday in Norway last summer, with a great sorrow, not even dulled, as his shadow, he probably walked harder than was wise. Whether over-tired or specifically infected, he came home under a cloud of nervous depression which became darker and darker until at the last it overwhelmed him.

Gemmill was an upright man, reverent, good through and through; he was frugal and abstemious, fond of his kindred and friends, full of kindliness to all men of good-will. He liked simple pleasures—always keen on a walk; he loved children; he delighted in his garden, his study-aquarium in Glasgow days, the flowers of the field, his pets—the dog most of all. He enjoyed meeting people when the day's work was done and he had a talent—perhaps a genius—for friendship. That he was pre-eminently interested in zoology is obvious, and he once told us that he was glad that amid ups and downs he had been able to hold by an early resolve that he would allow nothing—even teaching—to come between him and investigation. Often we pressed him to write a book, for he had very individual ideas, about organic evolution, for example, combining Lamarck's outlook with Goethe's, but he always resisted what he smilingly called a "temptation." We must think of Gemmill as one who made a great success of life, for he had the joy of many red letter days of discovery along the line which he had proposed to himself as his. Amid all his profound seriousness he greatly enjoyed Nature and many of the pleasures of human life; and was he not greatly beloved?

Why was it that we all, so different from one another, liked the man so much? Perhaps part of the reason was our quick discovery that he was thinking more about us than about himself. It was not only that he was overflowing with kindness, but he had also the rare gift of affectionate interest—half a naturalist's, half an artist's—in individuality. He took pleasure in our eccentricities; he delighted in our ruggednesses; he enjoyed our upsetting enthusiasms. Alas, alas, that there was no staying the Fury with the abhorred shears; but we doubt not that our friend will live on for his full span in the minds of many made better by his presence. J. A. T.

WE regret to announce the following deaths:

Prof. A. C. Eycleshymer, Dean of the College of Medicine of the University of Illinois, distinguished for his work on vertebrate embryology, on December 30, aged fifty-eight years.

John K. Hillers, an early member of the United States Geological Survey who, while in charge of the Photographic Laboratory of the Survey, was responsible for many photographs of noteworthy geological features of the western United States which have passed into text-books and reports, on November 14, aged eighty-two years.

Dr. Martin Murphy, president in 1902–3 of the Canadian Society of Civil Engineers, distinguished for his work on railway bridge-building, on January 10, aged ninety-four years.

The Hon. Sir H. A. A. Nicholls, lately Principal Medical Officer of Dominica, West Indies, known for his work on tropical diseases and on tropical agriculture, aged seventy-four years.

Prof. H. Kamerlingh Onnes, For. Mem. R.S., for many years Director of the Physical Laboratory at the University of Leyden, and Nobel prizeman for physics in 1913, on February 21, aged seventy-two years.

M. Adrien Robert, of the Sorbonne, secretary of the Zoological Society of France, on November 16, aged fifty-eight years.

Dr. M. B. R. Swann, fellow of Caius College and demonstrator in pathology in the University of Cambridge, from blood poisoning contracted during a *post-mortem* examination, on February 16, aged thirty-two years.

Mr. J. Whytock, first president of the Botanical Society of Edinburgh and a recipient of the Victoria Medal of Honour of the Royal Horticultural Society, on February 1.

News and Views.

THE president and council of the Royal Society decided at their meeting on February 18 to recommend for election into the Society the following fifteen candidates: Dr. J. A. Arkwright, Dr. E. J. Butler, Lieut.-Col. S. R. Christophers, Prof. F. J. Cole, Mr. A. C. G. Egerton, Dr. Ezer Griffiths, Mr. H. B. Hartley, Dr. H. Hartridge, Prof. G. B. Jeffery, Prof. O. T. Jones, Prof. W. C. McCullagh Lewis, Prof. E. A. Milne, Mr. L. F. Richardson, Mr. H. T. Tizard, Prof. R. S. Troup.

THE following have been recommended for fellowship of the Royal Society of Edinburgh: Prof. K. W. Braid (Glasgow), Prof. A. E. Cameron (Saskatchewan), Mr. R. T. Francis (Purley), Mr. J. D. Gardner (Edinburgh), Prof. J. G. Harrower (Singapore), Lieut.-Col. W. F. Harvey (Kasauli), Dr. S. R. Khastgir (Edinburgh), Dr. N. S. R. Lorraine (Hull), Mr. J. A. M'Bride (Glasgow), Very Rev. Dr. D. MacKichan (Edinburgh), Dr. D. C. T. Meikie (Edinburgh), Mr. J. A. Morris (Ayr), Dr. D. Patton (Glasgow), Dr. B. Prashad (Calcutta), Mr. J. A. F. Roberts (Edinburgh), Mr. W. H. C. Romanis (London), Colonel Sir Bruce Gordon Seton (Edinburgh), Prof. J. Small (Belfast), Dr. W. N. Stokoe (Edinburgh), Prof. G. H. Thomson (Edinburgh), Dr. J. Thomson (Glasgow), Mr. C. P. G. Wakeley (London), Mr. S. Williams (Glasgow).

A FURTHER stage in the development of the comprehensive scheme of irrigation for Egypt and the Sudan, forming a corollary to the work recently carried out at the Sennar Dam and described in the issue of NATURE of February 6, is detailed in the report, just issued by the Public Works Department of Egypt, relating the results of the mission despatched in 1920 to Lake Tsana, in Abyssinia, for the purpose of considering the possibility of converting the lake into an artificial reservoir. Lake Tsana is the source of the Blue Nile, which is controlled on the Gezira Plain by the Sennar Dam. The verdict of the mission is that the lake is eminently suitable for the purpose in question. The annual discharge during normal years is estimated at 3500 million cubic metres, and this is the amount that could generally be stored. But by certain engineering operations, including excavation of the rock sill at the outlet, it would be possible to increase the reserve storage to 8000 million cubic metres, which would be sufficient to meet deficiencies, if two seasons of low supply were experienced in succession. This reserve storage of 8000 million cubic metres, added to the annual supply of 3500 million cubic metres, would therefore give the reservoir a total effective capacity of 11,500 million cubic metres. The report estimates the cost of the work at £E2,300,000, and it is indicated that the work could be completed without the necessity of establishing any permanent means of communication with the Sudan; but if a railway or road to Gedaref should be found necessary, an increase in expenditure would follow. The Abyssinian Government has regarded the matter favourably and given its co-operation in the investigations. It is hoped, therefore, in view of the fact that the waters of the lake are of no service to the inhabitants for irrigation of its shores, while they would undoubtedly be of considerable value to Egypt and the Sudan, that the Abyssinian Government will grant at an early date the desired facilities for constructing the proposed regulation works.

THE Department of the Interior, United States Geological Survey, has just published the statistical summary of petroleum production and consumption for the year 1923, from the compilation of Mr. G. B. Richardson. In this memorable year all previous records for the output of crude petroleum in the United States, and, incidentally, for the world, were broken by the production in that country alone of 732,407,000 barrels of oil, constituting 72 per cent. of the total world's output for that year. This figure also implies a 31 per cent. increase on the output of the United States for the previous year, and was attained largely as the result of flush production from a number of rich pools, the maximum yield of which occurred during this year. The domestic production of the country was further augmented by imports of crude oil amounting to 82,015,000 barrels, thus creating a record total supply of oil in America of 814,422,000 barrels. Consumption, on the other hand, was less than domestic production, for the first time since 1914.

THIS extraordinary output of petroleum in 1923 created a serious phase of over-production and brought with it a corresponding slump in prices of crude oil and a depressed state of the oil industry generally, from which recovery has been slow. Since 1923 a considerable body of opinion has been expressed that that year's production of petroleum represented the 'peak' of the United States, and probably of the world, and some rather gloomy forebodings regarding the future of petroleum supplies have been voiced, both in the United States and in Europe. For many reasons there may be expressed some doubt on this point, though it is not denied that once the peak is definitely passed, the life of petroleum supply may be a comparatively short one at the present rate of consumption. On the other hand, the advent of a new pool comparable with any one of those responsible for the flush production of 1923 would quite possibly bring an annual total up to that of that particular year; and as there is no reason to suppose that the last 'bonanza' oil-pool has been found, there is still some hope that 1923 was not the 'peak-year' of either United States production or of that of the world.

A REFRIGERATOR which is claimed to be the only known contrivance for the continuous production of cold without the use of mechanical moving parts was brought before a large gathering at the Savoy Hotel in London, on February 23. The machine is being put on the market as the Electrolux Refrigerator (153-155 Regent's Street, London, W.1). It operates on the Platen-Munters system, ammonia being used as the working fluid, and hydrogen is employed to keep the pressure uniform throughout the plant. A cylindrical iron vessel containing a solution of ammonia is heated, preferably electrically; the water vapour is condensed and runs back into the 'generator,' and the ammonia passes on, being condensed in a water-jacketted tube leading to the 'evaporator.' Here it descends over baffle plates and evaporates, producing a lowering of temperature of the 'evaporator' and non-freezing solution surrounding it, and so of the chamber which it is required to cool. Ammonia gas, with the hydrogen filling the plant, passes down the 'evaporator' to the 'absorber,' where it meets a weak solution of ammonia running under gravity from the 'generator.' The ammonia is absorbed and passes back to the 'generator' by an ingenious 'trap' actuated by the heating element, while the hydrogen released goes on again to the 'evaporator.' The whole apparatus is of iron and is sealed, and there are no mechanical parts to require attention. Small plants only were shown, but other models are being produced.

THE prevalence and danger of insect pests in connexion with the growing of cotton led the Department of Agriculture in the Tanganyika Territory in 1922 to establish rules concerning the cotton crop. Two of the rules provide for the uprooting and destruction of all cotton refuse remaining at the end of the cotton growing season. A leaflet entitled "What to do at the end of the cotton season and why?" has been issued recently to planters and native cultivators. The dangers and breeding habits of insect pests, such as the red cotton-stainer and pink boll-worm, are pointed out, and reasons are given for the rules prescribing the uprooting of cotton and the destruction of wild plants allied to cotton at the close of the season. 'Ratoon' cotton in Tanganyika tends to harbour such insect pests and provides a ready source of infection for the new crop in the succeeding season, for such 'ratoon' plants produce bolls much earlier than the plants of the new crop. Similarly, dead stalks and other refuse from the cotton crop, if not destroyed, harbour the pests during the period between crops. Weeds such as Hibiscus and trees like Bombax (Eriodendron) may also enable the pests to carry over from season to season. The leaflet thus advocates thorough cleaning up of all plantations, as early as possible, pointing out that the earlier the clean-up the longer will be the famine period for the insects. The leaflet is printed in English and in the native language.

SEASONAL forecasting in India has been developed for some years, and considerable progress has been made in the application of statistical methods to weather prediction. A memorandum on the probable character of the weather in north-west India in January, February, and March was issued last month by Mr. J. H. Field, Director-General of Indian Observatories. Out of four principal factors available, two are practically neutral; these are the December rains at Port Blair and the pressure at Seychelles in November and December. The December rains in the western region were adverse, while the factor of rainfall at Seychelles in November and December and at Zanzibar in December was favourable. The seasonal change of the upper-air currents in northern India at a height of 3 to 5 miles above sea-level promises to prove of importance as observations accumulate; the prospect of winter rains from November to March for north-west India bears a close relation with the relative vigour of these high-level winds during the latter half of September and in October. The factor of the upper winds indicates a slight excess of precipitation. The final conclusion from all data available is that the winter precipitation, rain and snow, in north-west India is likely to be normal.

UNDER the title of "The Botanical Case for Evolution," the veteran palæobotanist, Dr. D. H. Scott, writes entertainingly and instructively in the *Nineteenth Century* for February. Pointing out that the experience of plant-breeding, whether carried out by the cultivator or the experimenter, shows that species are often not unchangeable, he bases the case for evolutionary change in Nature upon the following grounds: (1) Classification and its recognition of affinity, most readily interpreted in terms of descent; (2) the fundamental unity of organisation throughout the living world; (3) the comparison of organs and structures in different groups of plants, which show us an organ functional in some species, useless in others, turned to fresh uses in yet other species, etc.; (4) the geological record, in spite of such 'abominable mysteries' as the sudden appearance of the flowering plants in the Cretacean period. In his concluding remarks Dr. Scott quotes with evident sympathy from Witham of Lartington, the first to investigate the structure of fossils, who wrote in 1833: "To lend my aid in bringing from their obscure repositories the ancient records of a former state of things with the view of disclosing the early and mysterious operations of the Great Author of all created things will ever be to me a source of unalloyed pleasure." There can be little doubt that for Dr. Scott, too, it has been an unalloyed pleasure to attempt to disclose the "early and mysterious operations" in the history of the vegetable kingdom, and the result has been the great series of monographs, and still more the 'Studies' through which most of the present younger generation of botanists first make their acquaintance with the flora of the past.

THE anthropometric measurements made in the schools of England and Wales as a part of medical inspection are intended primarily as a test of physique and, except in a limited degree for specific purposes, or experimentally, their correlation with mental characters has not been attempted. The difficulty of any extended investigation of mental characters lies in securing uniformity in standard when anything involving a process which is not susceptible of a straightforward mechanical record is attempted. This difficulty vitiates to a certain extent some interesting investigations made by Dr. Arthur MacDonald of Washington, D.C., in which he has attempted to correlate mentality with physical measurements. A summary of his results was given in the *Medical Times* for November. According to his figures, dolichocephaly both as an individual and as a racial character appears to be associated with dulness and unruliness; brachycephaly with brightness; further, that both dolichocephaly and dulness increase after puberty, while brachycephaly decreases. He also records some interesting and rather surprising results relating to the correlation of physique and individual history of disease in students. Dr. MacDonald's figures must be taken for what they are worth, and although based upon a large number of observations, his inferences should be accepted with reserve. He attributes to anthropologists some sweeping conclusions on head form which few would endorse without qualification. It is scarcely necessary to point out the value to educationists of research which would show a valid correlation between physique and mentality to be generally applicable, even on the broadest lines, and not confined to abnormalities.

THE latest annual report of the Bristol Museum and Art Gallery records the offer of Sir George A. Wills to provide an extension of the building on the recently acquired site of the old Drill Hall, at a cost not exceeding 75,000*l*. The offer, which was accepted "with intense gratification," provides for a new Art Gallery to the plans of Messrs. Frank W. Wills and Sons, the architects of the existing gallery. This will occupy a little more than one-third of the whole site; the present gallery will be devoted to ethnography and antiquities, again about one-third; while the remaining third will be entirely available for the natural history collections, except for the large lecture-theatre serving the whole. Important bequests recorded comprise a collection of foreign lepidoptera, formed by the late Mr. G. C. Griffiths; a collection of big-game heads and native weapons, from the late Sir William Garstin; and a collection of British and foreign birds and 120 Baxter and Le Blond prints, from the late Mrs. Dalton-Burgess. The fine collection of engravings formed by Mr. Heber Mardon and presented by deed of gift in 1919 together with his extra-illustrated copy of Nicholls and Taylor's "Bristol Past and Present," in fourteen large volumes, was handed over by the family on Mr. Mardon's death in 1925. All this has thrown much work on the staff, and it is the more satisfactory to note that the valuable geological collections of the Museum are being made more accessible than they have been for many years, and that important specimens have been brought to light. Alderman Eberle and Dr. Herbert Bolton are to be congratulated on a report that shows progress in every direction.

THE British Museum (Natural History) is issuing a remarkable series of picture postcards illustrating many of the most interesting specimens contained in the Museum collections. A particularly attractive set of these cards, lately published, includes selected representations of exotic butterflies, moths, beetles, homoptera, heteroptera, and orthoptera. The figures are admirably executed in colour, and each packet of five cards (price 1*s*.) is furnished with an explanatory leaflet giving a concise account in general terms of the group or subject illustrated, and directing especial attention to any points of interest shown by the specimens represented. Thus, the letterpress contained in one of the packets devoted to butterflies gives a general account of the curious phenomenon of seasonal variation in these insects, and then proceeds to a brief but accurate description and discussion of the examples represented on the accompanying cards. These comprise figures, beautifully executed, of three striking African forms, in two at least of which, *Teracolus achine* (a "white" butterfly, or Piernie) and *Precis octavia* (a nymphaline allied to our Peacock and Red Admiral), the differences between the seasonal phases are so great that they were long held to be distinct species. Another packet contains excellent figures of some of the splendidly coloured Swallowtails of South America, and directs attention, in its accompanying notes, to the mimicry of other South American butterflies adopted by some members of the group. The brilliant colours exhibited by several of the grasshoppers, beetles, bugs, and moths represented in other packets will be a revelation to many whose acquaintance with these groups is only slight. These features are well brought out by the method of representation employed, and the claim of the Museum, that as much care has been taken with the figures as if they were destined to illustrate scientific monographs, is completely justified.

WE are informed that the Museum of Practical Geology, 28 Jermyn Street, S.W.1, is closed for repairs until further notice. Access to the Library and Offices of H.M. Geological Survey may be obtained through the entrance in Piccadilly.

PROF. KARL VON DEN STEINEN, Berlin, world known by his anthropological explorations in Central Brazil, and Baron Erland Nordenskiöld, of the Göteborg Museum, have been elected honorary members of the Paris Société des Américanistes.

DR. F. A. BATHER, keeper of the department of geology, British Museum (Natural History), has been elected a foreign member of Die Kaiserliche Deutsche Akademie der Naturforscher zu Halle. This is the oldest scientific academy in the world, having been founded in 1652.

WE learn from *Science* that a physico-chemical institute, to serve as central laboratories for scientific work in Spain, is assured by a gift of 40,000*l*. from the Rockefeller Foundation. The site of the building will be provided by the Spanish Government. It will probably be near the Museum of Natural Sciences in Madrid.

PROF. A. S. EDDINGTON will deliver the Bakerian Lecture of the Royal Society on May 6, taking as his subject "Diffuse Matter in Inter-stellar Space." The Croonian Lecture will be delivered by Prof. A. V. Hill on the "Laws of Muscular Motion" on May 20. On March 4, a discussion on "The Electrical State of the Upper Atmosphere" will be opened by Sir Ernest Rutherford

THE Botanical Society of America, at its recent meeting in Kansas City, Missouri, elected the following corresponding members: Profs. A. Engler and K. Correns, of the University of Berlin; Prof. C. Sauvageau, of the University of Bordeaux; S. Nawaschin and Prof. R. Willstätter, of the University of Munich Previously elected corresponding members are Profs. V. H. Blackman, F. C. Bower, Hugo De Vries, K. von Goebel, and A. C. Seward.

A MEETING will be held at the rooms of the Linnean Society on Wednesday, March 10, at 3.30 P.M., to consider a suggestion that the fifth International Botanical Congress should be held in London in 1930, and, in the event of the suggestion being adopted, to formulate an invitation to be submitted to the ensuing fourth International Botanical Congress at Ithaca, U.S.A., in August next. The Hooker Lecture of the Linnean Society will be delivered this year by Prof. Carl Schröter, foreign member of the Society, of Zurich, on April 15, and will be entitled "The Swiss National Park and Scientific Researches into its Nature."

THE Empire Council of Mining and Metallurgical Institutions, Cleveland House, 225 City Road, London, E.C.1, on behalf of ten constituent bodies, has accepted the invitation of the Canadian Institute of Mining and Metallurgy to hold the second Empire Mining and Metallurgical Congress in Canada in August-September 1927. It will be recalled that the first Congress, from which the Empire Council arose, was held at the British Empire Exhibition, Wembley, in 1924, under the presidency of the late Viscount Long of Wraxall.

THE Royal Academy of Sciences in Sweden has appointed a committee, consisting of Prof. Osten Bergstrand, of Upsala, Prof. C. V. L. Charlier, of Lund, and Profs. Karl Bohlin and V. Carlheim-Gyllensköld, of Stockholm, to organise the celebration of the 350th anniversary of the foundation of Tycho Brahe's "Uraniborg"—the city of the heavens. This magnificent observatory, famous in the history of astronomy, was built in 1576 on the island of Huen, which was granted to Tycho Brahe for life by Frederick II., King of Denmark. The island now belongs to Sweden.

IN the House of Commons on Thursday, February 18, Mr. MacDonald presented a petition at the request of his co-Trustees of the British Museum. The petition recited the capital holdings which the Trustees had and the income derived from the holdings, and stated that the income was not sufficient to enable the Trustees to carry out their trust efficiently. In conclusion, the Trustees asked for "further support towards enabling them to carry on the execution of the trust reposed in them by Parliament for the general benefit of learning and useful knowledge."

ON the initiative of the Orientalists' Association of Leningrad, it is proposed to hold the first International Exhibition of Buddhism at Leningrad in the autumn of 1926. The nucleus of the exhibition will be furnished by the rich Buddhist collections of the Russian Museum of the Orientalist Association and of the Asiatic Museum of the Academy of Sciences. Japan, China, Tibet, Mongolia, and other countries will be represented. The Academy of Sciences has despatched Prof. Stcherbatsky to Japan and Prof. Alexeiev to China to collect exhibits.

IT is announced that further collections of objects discovered by Col. Kozlov in Mongolian mounds have been received at Leningrad. These include both Greek objects and objects of local manufacture showing Greek influence. Among the more remarkable are Greek fabrics and embroideries with designs of flowers, birds, and human figures in the Greek style. Particularly noteworthy is a piece of embroidery showing a group of horsemen. The Greek ornament and the Scythian dress, headgear, and harness of the horsemen suggest that the embroidery is derived from one of the Græco-Scythian settlements of South Russia.

THE Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation was established in the first place for the encouragement of medical and allied research, grants being made for the purchase of special apparatus and supplies and preference being given to researches on a single problem. According to the second annual report recently issued, thirteen grants varying from 40*l.* to 340*l.* were made last year, four of which were for investigations on chronic nephritis. Five of last year's grants were to workers in Europe. Applications for grants for the year 1926–27 should reach the secretary of the committee of the Foundation at Boston City Hospital, Boston, Massachusetts, before May 15.

Two awards are announced in the January issue of the *Journal of the Franklin Institute*; the John Price Wetherill Medal to Mr. F. Twyman, London, and the Edward Longstreth Medal to Mr. T. Midgley, Dayton, Ohio. The award to Mr. Twyman is for the Hilger interferometer, which provides a simple and accurate method of locating and correcting imperfections in prisms and lenses. It will be recalled (NATURE, July 14, 1921, p. 635) that in this instrument a beam of monochromatic light is divided into two parts, one of which is passed twice through the object under test. The two beams are recombined so as to produce a set of interference bands which form a "contour map" of the imperfections of the optical element under test. The award to Mr. Midgley is for the Midgley optical indicator. This instrument is a high-speed indicator for use with internal combustion engines. A beam of light falls upon a mirror the position of which is determined by the position of the piston in the cylinder. The light is reflected to a revolving mirror the position of which depends on the second element required, and a pressure-volume or pressure-time curve can be obtained. Novel methods of reducing inaccuracies due to inertia of moving parts are adopted and the use of a spring and piston in the pressure element makes it possible to use a uniform scale for the entire height of the pressure card.

THE provisional programme of the Optical Convention, 1926, which has now been issued, shows that every effort is being made to ensure that the Convention will provide a comprehensive and complete survey of British contributions to optics in recent years, and of the position of optical science and the optical industry at the present time. The Convention will be held, under the presidency of the Astronomer Royal, at the Imperial College of Science, South Kensington, on April 12-17 inclusive. Scientific and technical papers, dealing with every branch of theoretical and applied optics, will be read and discussed, and special discourses will be given, including lectures of a popular character accompanied by demonstrations. The most modern types of optical instruments and apparatus will be exhibited by British manufacturing firms in all branches of the optical trade. There are also to be exhibits illustrating the results of recent optical research and the application of optical methods in the laboratory. Demonstrations and dramatic performances, incorporating various interesting optical illusions and projection effects, are being specially composed for presentation during the Convention. Particulars of membership of the Convention and forms of application may be obtained from the Secretary, 1 Lowther Gardens, Exhibition Road, S.W.7.

THE technical programme has now been issued of the sectional meeting organised by the Swiss National Committee of the World Power Conference to be held at Bâle on August 31–September 12 next. The work of the meeting will be divided into five sections dealing with the utilisation of water power and inland navigation, exchange of electrical energy between countries, hydraulic and thermal production of electrical energy, electricity in agriculture, and railway electrification respectively. Contributions will be regarded as National Papers (presented on the initiative of a national committee or of a member of the International Executive Committee) or Reporters' Papers (prepared by general reporters appointed by the Swiss National Committee, summarising national papers presented before April 1 and emphasising definite aspects of the subjects discussed). Papers and discussions are to be published in a volume of proceedings. Communications for the British National Committee should be addressed to the Secretary, World Power Conference, 36 Kingsway, London, W.C.2.

H.M. STATIONERY OFFICE announces for publication at the end of the month a special edition of the "Nautical Almanac 1928" bound in cloth boards; the edition in wrappers is also available. The edition in cloth will be continued in future years if it is found to meet a public need. Both editions may be obtained from Mr. J. D. Potter, 145 Minories, E.1.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in pharmaceutical and general chemistry at the School of Pharmacy of the Pharmaceutical Society of Great Britain—The Secretary of the Society, 16 Bloomsbury Square, W.C.1 (April 12). A professor of zoology in the University of Calcutta — The Registrar, University of Calcutta, Senate House, Calcutta (April 12). An assistant lecturer in mathematics in the University of Leeds—The Registrar (April 21). A principal for the proposed University College for Hull—The Secretary to the Board of the College, Guildhall, Hull (May 1). Lecturers in historical geography and physical geography at University College, Reading—The Registrar. An honours graduate in physics as assistant under the British Research Association for the Woollen and Worsted Industries —The Secretary, Torridon, Headingley, Leeds.

Our Astronomical Column.

RECENT SUNSPOTS.—In our issue of February 20, p. 282, mention was made of the third appearance of a spot in south latitude 21°. When more fully on the sun's disc, it could be seen with the naked eye, and should therefore be included in the list of naked-eye spots, as follows:

No.	Date on Disc.	Central Meridian Passage.	Latitude.	Area.
4	Feb. 13–25	Feb. 19·1	21° S.	1/2000

The spot was typical of a regular spot with well-defined filamentary structure of the penumbra and stable outline. It may be expected to return at least once again, though probably as a telescopic object only.

As noted last week, the great spot of January returned, but it was only about one-sixth of its previous size. It was accompanied, however, by a very extensive region of bright faculæ, seen easily when near the sun's limbs with a small telescope.

Spot No. 3, which was on the sun's central meridian on February 15, decreased rapidly and was of less than naked-eye visibility by February 16.

THE TEMPERATURES OF THE PLANETS.—The issue of the *Physikalische Zeitschrift* for December 23, 1925, contains a report by Dr. E. Schoenberg on the present state of our knowledge of the temperatures of the planets. For planets still in the gaseous state there is as yet no satisfactory theory connecting the radiation sent out with the temperature distribution, but for those having solid crusts, either with or without atmospheres, Milankowitsch in his recent book has provided a satisfactory theory, which the author reproduces in the earlier sections of his report. He then describes the radiometer measurements made during the past twelve years at the Lick and Arizona observatories, and gives as the most reliable values of the surface temperatures: Venus 45° C., Mars −15° C., Jupiter and Saturn −80° C., the value for Venus being somewhat doubtful, but the others much more trustworthy. Dr. Schoenberg concludes his report by describing a method he has devised, and already applied to the visible portion of the spectrum, for determining the density and temperature of the atmosphere of a planet at any depth below the visible surface, by photometric measurements of the twilight band at the terminator, his theory being that the brightness of this band is due to diffusion only, and not to absorption.

Research Items.

Megalithic Works in Fiji.—In *Man* for February, Mr. James Hornell figures and describes some of the megalithic sea works and temple platforms at Mbau in Fiji. Mbau is the most historic place in Fiji and was the seat of government of Chief Thakombau, who in the middle of the last century brought many of the other chiefs under subjection. The sea works which are described consist of a number of docks and piers into which the big outriggers and double canoes were run. Of these docks there are now twenty-five, some of which were made during the latter part of the last century by dividing up the larger docks. The sides of the wharves are protected in three different ways, of which the most characteristic is by means of large slabs of rock set on edge, of various sizes running up to 11 feet 8 inches in height. Little attempt has been made to shape them. The most important of these docks was probably the ceremonial landing-place of the head of the dominant community. Prisoners of war were possibly also landed here and brained for the ceremonial feast. As regards the age of these structures, a comparison with a similar structure at Mua (Tongatabu), which may be connected with the sons of the Tongan king Tui-ta-tui, suggests the end of the thirteenth century as a possible date.

Psychical Methods in Medicine.—In *Psyche* (January 1926) Dr. F. G. Crookshank contributes an interesting article entitled " Spiritual Healing in the Light of Modern Medicine." He directs attention to the lamentably slack use of terms implied in such phrases as organic versus functional disease, suggestion and faith healing, physical versus psychical methods of cure, which phrases, he thinks, have long outlived their usefulness. He pleads for a stabilisation of verbal symbolism on a basis of real values. Although physicians profess to have no metaphysical prejudices, much of their actual practice is based, not on any assured basis of observation, but on the dregs of the psycho-physical parallelism of the last century. The result has been a neglect of the functional neuroses by the orthodox physicians. The antinomy between functional and organic disease was invented in order that " we might say that organic disease is what we say we cure but don't, while functional disease is what the quacks cure and we wish to goodness we could " ! Actually, the so-called physical and the so-called psychical methods are indistinguishable objectively, and the prescriber of drugs is often aware that faith plays no small part in procuring the efficacy of the drug. He believes that the scope of psycho-therapy is coterminous with the whole range of disease, though never to the exclusion of what we call physical methods Wherever there is scope for psycho-therapy there is a mental conflict, and this is present far more frequently than is imagined in cases deemed to be suffering from organic disease only. But it is necessary to adopt a changed attitude in respect of the mind and matter controversy. Dr. Crookshank protests against the assumption that the rational foundations of science are all well laid, and he maintains it is unscientific to reject testimony of strange occurrences just because such are thought incompatible with what we call science. The article is thoughtful and provocative, and is worthy of consideration by all those whose work involves dealing with people, whether in the capacity of physician, teacher, preacher, or employer. It is well at times to revise one's assumptions.

Action of X-Rays on the Developing Chick Embryo.—Drs. Colwell, Gladstone, and Wakeley (*Jour. Anat.* 60, pp. 207-28, January 1926) give an account of a series of experiments designed to test the effect of X-rays on the developing embryos of the fowl. In an earlier paper the authors concluded that, in embryos irradiated immediately before incubation and then daily for several days, the action was always inhibitory, the irradiated embryos being invariably smaller than the controls Those which received the full pastille dose of X-rays were most affected, six out of nine showing no development at all. In all those showing development, all tissues and organs which should normally be developed were differentiated but smaller in size. The effect was therefore one of retardation or diminution of growth. In the present paper the authors give the results of experiments in which the embryos were allowed to develop normally for four days and then subjected, in two groups, to daily irradiation of three and five days respectively. In these cases there did not seem to be any marked effect on the average length of the embryos compared with controls. The principal action of the rays appeared to be their destructive effect on the tissues, exerted chiefly on the cutaneous ectoderm, the neural tube and its associated structures, the epithelium of glandular structures such as liver and mesonephros, and on the red blood corpuscles. The effects showed themselves in detachment of the epithelium, in a diminution in the transparency of the cytoplasm, and in the formation of granules or vacuoles in the latter.

Citrus Fruit in the Philippines.—According to A. H. Wells, F. Agcaoili, and Maria Y. Orosa of the Bureau of Science, Manila, there are about eight hundred types of citrus growing in the Philippines, including the valid indigenous species, the hybrids, and the introduced species. At the same time there is not a single citrus plantation on modern commercial lines in the islands, whilst, on the other hand, the Filipinos seem to appreciate the fruit as the returns of the importation of citrus into the islands demonstrate. The Lamao Experiment Station has now shown that quite good produce can be obtained upon trees of commercially valuable types when grown under Philippine conditions, and the authors urge that citriculture should be taken up by the inhabitants upon a commercial scale. Their paper in the *Philippine Journal of Science* (vol. 28, No. 4, December 1925) contains particulars of the very complete selection of types of citrus under experimental cultivation in the Philippines, and also of chemical analyses of the fruits of selected varieties.

Contributions to Plant Physiology.—The numerous investigations recorded in Year Book No. 24, issued by the Carnegie Institution of Washington, include reference to the continuation at the laboratory of plant physiology at Tucson, Arizona, of work on desert succulents. V. Úlehla shows, by auxograph records of the swelling of succulent tissues in solutions of different concentration, that the methods developed by Ursprung and Blum for determining suction pressure, require supplementing by further experimental methods before valid conclusions as to suction pressure values can be drawn with safety. The work also emphasises once more the very complicated nature of the phenomenon of plasmolysis. H. A. Spoehr and Paul C. Wilbur show that in the presence of disodium phosphate and sodium pyrophosphate the aldose sugars are converted into the ketoses, and vice versa A noteworthy feature of this form of the von Eckenstein reaction is the disappearance of reducing power with time; this suggests that the reaction is not a true equilibrium but that the hexose molecule itself is being split. An interesting contribution to our knowledge of the absorption of carbon dioxide by leaf-powder is made by H. A. Spoehr and William Newton. From an ether water extract of the leaf-powder an equal volume of 95 per cent. alcohol throws down a precipitate of a substance which absorbs considerable quantities of carbon dioxide, and of which some of the reactions are given.

British Post-Pliocene Unionidæ.—Owing to the fragile nature of their shells, the Unionidæ found fossil in the Pleistocene deposits are commonly fragmentary and the discrimination of the species is difficult. A. S. Kennard, A. E. Salisbury, and B. B. Woodward (*Proc. Malacol. Soc.* 16, 1925, p. 267) give an account, illustrated by twelve photographic plates, of the British species, which will be of value to workers in Pleistocene geology. The external form of the shell, owing to its variability, is of little use in distinguishing species. The features of specific value are seen in the muscle scars, the hinge, and the umbonal rugæ.

Ammonites from the Upper Kimmeridge Clay.—A pleasing quarto-publication by Dr. E. Neaverson on the Ammonites from the Upper Kimmeridge Clay has been issued as one of the Papers from the Geological Department of the University of Liverpool. The memoir deals mainly with the small group of the so-called *Ammonites biplex* (more recently referred to as *Olcostephanus pallasianus* auct.) of the Upper Kimmeridge Clay. They are now described in detail and with care for the first time, and they are referred to a number of genera and species; but Dr. Neaverson remarks that the large majority of specimens are flattened by pressure and form "hopeless" material for investigation. The characters relied on by the author for subdivision are the general form of the suture-line and the developmental stages shown by the ammonites. Unfortunately, the author has not been able to dissect any species of, for example, his first genus (Virgatosphinctoides), and he figures only one complete suture-line, belonging to an undetermined species of doubtful generic affinity. The genus Virgatosphinctoides, we are told, includes Mr Pringle's Pseudovirgatites from the Oil Shales of Kimmeridge; and Dr. Neaverson, whilst expressing the "belief" that the phenomenon of homœomorphy is responsible for the similarity between the two groups, leaves the determination of possible relationship to future research. There is no indication that the author has studied the Volgian Virgatitids of Russia any more than the Mediterranean genera, except in published figures; and recent literature is not sufficiently noticed. The arrangement of the various ammonites into separate lineages thus reflects a somewhat limited outlook. The work, however, was obviously done conscientiously, and the four plates are good.

Grass Minimum Thermometers.—The Meteorological Office, Air Ministry, in Professional Notes, No. 43 (London: H.M. Stationery Office, 1925, price 6*d.* net), publishes "Some Effects produced by Protective Shields on the Readings of Grass Minimum Thermometers," by Mr. J. M. Stagg. At cold periods in such winters as the present, the thermometer exposed at night to radiation over grass gives some low readings of interest, at times 10° F. or even more below the reading of the ordinary air temperature in the Stevenson screen close by. The position of the grass minimum thermometer screened by a wire cage is well shown by illustrations, and observations are made of the thermometer screened and of a similar thermometer outside the cage, but unscreened, near by. The results are obtained from five series of experiments conducted at Kew Observatory, which is ample guarantee of correctness, and the observations are carefully collated. The paper sums up with final recommendations for observers. It is asserted that any form of screen in the vicinity of a grass minimum thermometer will result in an increase of the temperature recorded, and it deprecates a screen even situated entirely on one side of the grass thermometer. To those accustomed to obtaining radiation temperatures, it is well understood that lower temperatures and a greater difference between the Stevenson screen thermometer and the radiation temperature is obtained by placing the radiation thermometer, filled with clear white spirit, on short grass, with the bulb just touching the tops of the blades of grass, but on no account embedded in the grass. The stem of the thermometer should rest on a small fork of wood to raise the bulb.

The Compton Effect.—The issue of the *Journal de Physique* for December 1925 contains a summary of the spectrographic observations of M. de Broglie and A. Dauvillier on this effect during the last two years. Compton discovered in 1923 that when homogeneous X-radiation is scattered by a solid, the scattered radiation contains, in addition to rays of the same wave-length as those incident, rays of longer wave-length; he explained this effect as due to the impact of a quantum of the incident radiation on an electron, which recoils carrying with it some of the energy, and the decreased energy of the scattered quantum manifests itself in an increase of the wave-length of the radiation it emits. Duane and his colleagues failed to verify Compton's observations, but the researches of de Broglie and Dauvillier on the scattering of the *K*-radiations of tungsten, silver, tin, copper, and zinc by graphite, boron, glucinium, and aluminium confirm the original observations and are in agreement with the theory by which Compton explained them.

Separation of Platinum Group Metals.—A new method of separation of iridium, rhodium and platinum, one of the most difficult tasks in chemical analysis, is published in the *Scientific Papers of the Institute of Physical and Chemical Research, Tokyo.* Titanous sulphate solution precipitates rhodium and platinum, while iridium remains in solution with the titanium. The iridium is precipitated by reduction of the acid solution with hydrogen sulphide in the presence of a suitable amount of glycerol. The platinum and rhodium mixture is treated with aqua regia, the undissolved rhodium filtered off, the solution reprecipitated using an aluminium plate, and the precipitate fused with potassium hydrogen sulphate, which on treatment with water leaves the platinum in an insoluble form.

Mixed Crystals of Silver Halides.—The results of X-ray analysis of mixed crystals of silver chloride and bromide and silver bromide and iodide by R. B. Wilsey have been published in the *Journal of the Franklin Institute* for December 1925. The powder crystal method of Hull was employed and showed that the chloride-bromide mixtures have the simple cubic structure, while most bromide-iodide mixtures contain two mixed crystals, one the bromide with enlarged lattice spacing, and the other the iodide with a slightly smaller lattice constant. The enlargement of the bromide lattice predicted by Trivelli seems to be connected with the increased speed obtained with photographic emulsions of silver bromide with small amounts of silver iodide.

The Report of the Medical Research Council.[1]

A FIRST perusal of the report of the Medical Research Council for 1924–1925 shows its many-sided activities: there appears to be scarcely a branch of medical science in which investigations have not been carried on by members of the Council's staff or by other research workers receiving whole- or part-time grants. The great volume of work performed is due in great measure to the utilisation of facilities provided by the universities and other institutions, by means of grants-in-aid to the investigators working therein. Research work, therefore, throughout the country is co-ordinated through the medium of the Council; and as specific problems arise, plans for their investigation can be formulated and the work entrusted to those most qualified to deal with it. In addition, grants have been made for work within the programmes of the Department of Scientific and Industrial Research, the Miners' Welfare Fund, the Dental Board of the United Kingdom, the League of Nations, the *Field* Newspaper Distemper Research Council, and the British Empire Cancer Campaign. The Council also makes the annual awards of the Rockefeller Fellowships, tenable in America by scientific workers in the British Isles.

It must not, however, be supposed that any distinction is made between 'pure' and 'applied' research. Every advance in knowledge leads, sooner or later, to a practical application, even though the latter may not be at first apparent.

It is obvious that it is impossible to deal with all the many-sided activities of the Council in the space at our disposal; stress will be laid on certain outstanding pieces of work, more especially those which have not been recently considered in these columns.

An extremely important function of the Council is the regulation of biological standards: that is, standards for certain substances of unknown chemical constitution, or, if of known constitution, presenting difficulties in chemical estimation, or possibly showing a varying therapeutic potency, although apparently of the same composition. Two important steps have been taken during the year: the Therapeutic Substances Bill has received the Royal Assent, and the second International Conference on the standardisation of biological products was held at Geneva in September under the auspices of the Health Section of the League of Nations, when a gratifying measure of agreement was reached as to the standards for a number of products. The president of the Conference was Dr. H. H. Dale, to whom, to a large extent, the success achieved was due.

At present the only substances which are required to be biologically standardised in Great Britain are salvarsan and insulin; and this is only due to the fact that the patent rights are vested in a public department. The international conference agreed on standards for pituitary extracts, thyroid gland, digitalis and *Filix mas* and other anthelminthics; investigation is still proceeding with reference to standards for suprarenal preparations and adrenaline, ergot, and vitamin preparations. It may be anticipated that the compounds in the former group will shortly be scheduled under the Therapeutic Substances Act, so that preparations of or containing them will only be allowed to be marketed if they comply with the requisite standard. In this connexion it may be mentioned that Dr. Hartley has prepared a standard sample of diphtheria antitoxin; this is the only serum for which a standard and a method of assay have been accepted by international agreement at the present time.

The Standards Laboratory at Oxford, under Prof. Dreyer's direction, has supplied standard agglutinable cultures and standardised agglutinating sera made with certain of the enteric and dysenteric organisms; the quantities issued have been 195 litres of the former and nearly four litres of the latter. The National Collection of Type Cultures maintained at the Lister Institute under the direction of Dr Ledingham has been increased during the year, and more than 4000 type cultures have been distributed to research workers both at home and abroad.

Research work has been carried out in a number of specific subjects by numerous investigators. The oxygen chamber at Guy's Hospital has been in use again during the year, and great benefits are reported from this treatment in bronchitis and asthma. Dr. Edith Willock, working with Prof. Raper, has demonstrated the existence of an anoxæmic type of infantile atrophy, which is treated by means of oxygen-enriched air.

The physiology of hæmoglobin, the respiratory pigment of the blood, has been further investigated by workers under the direction of Prof. Barcroft Anson and Mirsky have shown that hæmochromogen—often called reduced alkaline hæmatin—is really a conjugated protein, consisting of a base, named 'hæm,' and globin, and have been successful in synthesising it. The base unites with many other nitrogenous substances besides globin, and gives a series of pigments, some of which are found in invertebrate animals. Dr. Keilin, investigating a respiratory catalyst called 'cytochrome,' has found it to be present in the cells of all ærobic organisms so far examined, including animals, higher plants, yeasts and bacteria; it appears to be formed of three hæmochromogen compounds and so to be closely related to the respiratory pigment hæmoglobin.

Prof. Shaw Dunn, working with Drs. Lovett, Dible and McSwiney, has investigated some aspects of acute experimental oxalate nephritis; it was found that water diuresis in this condition favourably influenced the urea retention, producing a copious elimination of the latter by the glomeruli. No diminution in the rate of blood-flow through the kidney was observed in this type of nephritis. Dr. Baker has described two cases of obstruction of the renal tubules caused by excretion of hæmoglobin following the intravascular hæmolysis of transfused blood. Experiments made later showed that hæmoglobin, excreted through the glomeruli in solution in an alkaline medium, is precipitated in the tubules, probably in the form of hæmatin, owing to the increase in acidity and salt concentration This intrarenal obstruction probably occurs also in blackwater fever The treatment suggested is the production of an alkaline diuresis. Prof. Maclean and Drs. Urquhart and Forest-Smith have been able to show that rabbits given an exclusively protein diet for long periods do not develop nephritis or, in fact, show any sign of renal impairment, provided they are also given small amounts of cabbage; previous results pointing to the opposite conclusion appear to have been due to a lack of vitamins or some other constituent of fresh food. Thus an excessively protein dietary does not appear to be harmful to the kidneys.

Prof. Korenchevsky and Miss M. Carr have been engaged in a research on the influence of the internal secretions of the sexual and prostate glands upon metabolism They conclude that the former contain hormones which increase the nitrogenous metabolism;

---

[1] Committee of the Privy Council for Medical Research Report of the Medical Research Council for the Year 1924–25. Pp 164. (London: H M Stationery Office) 3s. 6d. net.

the variable effects observed after injections of emulsions of either testes or ovaries are due not only to the specific hormones, but also to the presence of non-specific substances such as insulin, and to the varying efficiency of all the other endocrine glands in aiding or opposing the action of the hormones injected. Drs. Gardiner Hill, Jones and Forest-Smith have engaged in a study of different types of obesity and their relationship to the various glands of internal secretion. They consider that certain patients who present similar appearances to the diabetic receiving large amounts of insulin may be suffering from an excessive production or release of insulin from the pancreas.

Dr. Fletcher, working at Kuala Lumpur, has found that quinidine is as effective as quinine in the treatment of malaria, that the two alkaloids do not act specifically on one type of the malarial parasite, and that there is no difference in their toxicity. The question of the effectiveness and toxicity of the different cinchona alkaloids and their proportions in different species of bark is of considerable economic importance

Drs. Henry, Lewis, Chalmers and Harries have been investigating the toxin of the *Streptococcus scarlatinæ*; a stable preparation was obtained by precipitation with alcohol. Intradermal inoculation into human beings enables those who are susceptible to be distinguished from those who are relatively resistant; most young children are in the former group, and most adults in the latter; but children who have had the disease are also resistant. An antitoxin has been prepared the clinical trials of which are at present in progress.

A short section is devoted to some of the main aspects of the work of the Industrial Fatigue Research Board. The direct practical applications of much of this work, carried out 'in the field,' need scarcely be emphasised. The scientific study of workers in the factories leads to the formulation of conclusions as to the most beneficial methods of carrying out the various types of work examined, which should lead both to greater comfort for the worker and also to an increased output. Thus Mr. Wyatt and Mr. Fraser have shown that the judicious introduction of rest pauses almost always has a good effect, the workers unconsciously responding by increased efforts, so that the output is greater in spite of the shorter time worked. Thus shorter hours with higher wages seem to be no remote possibility.

University and Educational Intelligence.

CAMBRIDGE.—The death, in tragic circumstances, of Dr. M. B. R. Swann, the senior demonstrator in the Department of Pathology, has been a serious blow to the University in general and the Department in particular. It is not yet a matter of common knowledge that during the last few years this particular school, under Prof. Dean's guidance, has been the centre of renewed activity. In the first place, pathology has been introduced as a subject in the second part of the Natural Sciences Tripos. Students who wish to obtain a more detailed knowledge of pathological problems and a closer insight into modern research than is entailed by the crowded medical curriculum can now receive well-organised instruction. In addition, they have a definite status and also the advantage of receiving some acknowledgment for their trouble; as a result, competent research workers are being trained. The new pathological and veterinary building will, when completed, afford suitable accommodation for more workers. The staff is very keen and not over-encumbered with elementary teaching, so there are good prospects of considerable progress.

LONDON.—A course of three free public lectures on "Hygiene" will be given (in English) by Dr Gustave Monod, at the Middlesex Hospital Medical School, on March 2, 3, and 4, at 5.30 o'clock, and one of four (also in English) on "The Evolution of the Nervous System," by Dr. C. F. Ariens Kappers, at University College, on March 9, 10, 11, and 12, at 5.30 o'clock.

MANCHESTER.—Dr. John Samuel Dunkerly, senior lecturer in zoology in the University of Glasgow, has been appointed Beyer professor of zoology and director of the zoological laboratory in succession to Prof. S. J. Hickson, who will retire in September next. Dr. Dunkerly, who was a student of Birkbeck College, London, graduated in 1908, and later studied under the late Prof. Minchin at the Lister Institute of Preventive Medicine. He became an assistant-lecturer at Birkbeck College, and in 1911 was appointed lecturer in zoology in the University of Glasgow. He was on military service from 1914 to 1918, and in 1920 was appointed senior lecturer in zoology at Glasgow, obtaining the degree of doctor of philosophy there. A number of Dr. Dunkerly's papers have been published in the *Transactions of the Royal Society of Edinburgh*, the *Quarterly Journal of Microscopical Science*, and in other journals. His investigations have dealt mainly with Flagellata and other Protozoa

---

THREE fellowships, each of the annual value of 200*l*. and tenable for two years, are being offered to graduates of the University of Wales. Particulars are obtainable from the Registrar, University Registry, Cathays Park, Cardiff. The latest date for the receipt of applications for the fellowships is May 31.

APPLICATIONS are invited for the Grocers' Company's research scholarships in sanitary science, each of the annual value of 300*l*. and an allowance to meet the cost of apparatus, etc, in connexion with the research carried out. The scholarships will be tenable for one year, but renewable for a second or third year under certain conditions. Forms of application (returnable not later than April 13) may be obtained from the Clerk of the Grocers' Company, Grocers' Hall, E.C.2.

FROM the Universities Bureau of the British Empire we have received a 40-page pamphlet containing lists of students from other countries in the universities and university colleges of Great Britain and Ireland, and of interchanges of teachers in 1924–25 between the universities of Great Britain and Ireland and those of other countries. A numerical summary of students from abroad discloses some interesting facts. The total number of the students in these lists is 4669. To this total Asia contributes 1718 (including 1301 from India, Burma, and Ceylon, 110 from China, 102 from Japan, 77 from Siam, 42 from Palestine, and 41 from Malaya), Africa 1150, America 815, and the Pacific 332. Of countries within the Empire, Canada and Newfoundland are represented by only 151, including 45 (chiefly Rhodes scholars) at Oxford, the West Indies, having no university of their own, send a much larger contingent proportionally to their population, namely, 139; South Africa and Rhodesia send us more than any other part of the Empire except India—716; from Australia there are 217, and from New Zealand 114. From foreign countries, the most notable contributions, other than those already mentioned, are: Egypt 351, United States 434, Russia 99, Germany 78, Switzerland 64, France 47 Of the universities most frequented by students from abroad, London is easily first with 2158 (including 673 in the medical schools). Next come Oxford 530, Edinburgh 525, Cambridge 493, Glasgow 207, Manchester 179.

Contemporary Birthdays.

February 27, 1864. Prof. Arthur G Green, F.R.S.
February 28, 1858. Mr. James Swinburne, F.R.S.
March 1, 1864. Prof. G H. Bryan, F.R.S.
March 2, 1870. Sir Frederick W. Keeble, F.R.S

Prof. Arthur G. Green was educated at Lancing College and University College, London. He was, from 1902–16, professor of tinctorial chemistry at the University of Leeds, afterwards director of research, British Dyestuff Corporation, resigning in 1923. Early in his career he was research chemist to a firm of aniline colour manufacturers in London, leaving to take up the post of chief chemist and manager of the colour works of the Clayton Aniline Co., Manchester. He has produced a number of new coal-tar colouring matters. For some years he was examiner in coal-tar products to the City and Guilds of London Institute.

Mr Swinburne was born at Inverness and educated at Clifton College. He was apprenticed at engineering works on the Tyne. Afterwards he was associated with Sir Joseph Swan in the erection and equipment of glow-lamp factories in Paris, and Boston, U S.A. In 1886 he took up the post of technical manager and designer to Crompton and Co., Ltd., becoming afterwards a consulting engineer. He was elected president of the Institution of Electrical Engineers for 1902–3. His inaugural address was entitled "Some Limits in Heavy Electrical Engineering." Mr Swinburne remarked that "the sort of tacit assumption that an engineer can never be a 'scientific man,' while a 'scientific man' can teach the engineer his business, cannot fail to annoy the engineer, and this feeling of annoyance is largely the cause of a great deal of opposition to technical, that is to say, really scientific education. The work of the electrical engineer is manifold. We should understand steam-engines, gas-engines, tramway matters, fuel questions, parliamentary matters, railway management."

Prof. Bryan, who has just resigned the chair of mathematics in the University College of North Wales, Bangor, was born at Cambridge and graduated at Peterhouse, of which college he is an honorary fellow. He was elected a fellow of the Royal Society in 1895 for his work and papers on thermodynamics and other branches of mathematical physics. In 1900 he was awarded the gold medal of the Institution of Naval Architects, for his paper "The Action of Bilge Keels." In the discussion on the memoir Mr R. E Froude described it as "most masterly" and a valuable contribution to the theoretics of rolling. Prof. Bryan is particularly well known for his pioneer mathematical work relating to problems of aeroplane construction and stability. In "Stability in Aviation," he brought together much original work on this subject, and the conclusions reached were of great value in indicating how exact knowledge of the principles of dynamical stability could be applied to the movements of aeroplanes He was awarded the gold medal of the Aeronautical Society in 1904.

Sir Frederick Keeble, Sherardian professor of botany in the University of Oxford, was educated at Alleyne's School, Dulwich, and Caius College, Cambridge. Formerly he was Assistant Secretary, Board of Agriculture (1919); Director of the Royal Agricultural Society's Garden, Wisley (1914–19); and editor of the *Gardener's Chronicle*, 1908–19.

Societies and Academies.

London.

Royal Society, February 18.—**A. Fowler**. The spectrum of ionised oxygen (O II). The spectrum of oxygen in the region λ 6750—λ 1850 has been investigated under different conditions, and particulars are given of about 400 lines which are attributed to the singly ionised atom (O II); 90 lines have been assigned to the doublet system and 68 to the quartet system. On the supposition that three of the doublet *p* terms form a Rydberg sequence, with 4R for the series constant, the value 93952 has been assigned to the term $2\,{}^2p_2$, and the values of other terms have been deduced. The term $2s$ thus derived suggests about 240,000 for the $1s$ term. The tabulated quartet terms depend upon an arbitrary value assigned to one of them. So far as a comparison can at present be made, the spectra of O II and N I, as expected, show a close similarity, the wave-numbers of several of the groups of lines in O II being approximately double those of the corresponding groups of N I.—**William A. Bone, F. R. Weston, R. P. Fraser**, and **D M. Newitt** · New experiments upon the combustion of well-dried carbon monoxide and oxygen mixtures. Pts I. and II As water vapour is progressively removed from a $2CO + O_2$ mixture, the 'minimum spark energy' necessary to fire it by condenser discharge sparks increases until, with a calcium chloride dried mixture, it becomes twenty-or thirty-fold as great as that required to fire it when saturated with moisture at 15° C A $2CO + O_2$ mixture, dried by six months' contact with pure phosphoric anhydride, can still be ignited and exploded, provided that a spark of sufficient energy be passed through it, although the gases display a much greater 'resistance' to combination than when even a minute amount of moisture is present. Phosphoric anhydride-dried $2CO + O_2$ mixtures can be easily exploded by increasing the pressure up to a certain point (5 to 10 atmospheres). The spectrum of the flame produced by the explosion of such a mixture at an initial pressure of 25 atmospheres, shows a continuous and diffused band spectrum, extending up to 2780 Å.U in the ultra-violet *without any 'steam lines' being discernible*. The conclusion is drawn that steam is not *essential* to the ignition and explosion of carbon monoxide and oxygen mixtures. Probably the ionisation of one (or both) of the combining gases is a necessary precedent to their combination, and the presence of even a minute quantity of steam promotes such 'ionisation.'—**W. A. Bone, D. M Newitt**, and **D. T. A. Townend**: Gaseous combustion at high pressures. Pt. VI. The explosion of argon- and helium-diluted knall-gases. In mixtures represented by $2H_2 + O_2 + 6R$, $2CO + O_2 + 4R$, and $2CO + O_2 + 6R$, where R represents helium or argon, at initial pressures of 10-150 atmospheres, in the hydrogen series, helium and argon act as monatomic diluents only, but in the carbon monoxide series, helium is also exercising some other influence.—**P. A. M. Dirac**: Quantum mechanics, and a preliminary investigation of the hydrogen atom. The quantum theory of multiply periodic systems is developed from the fundamental assumption that the dynamical variables do not satisfy the commutative law of multiplication, but satisfy instead certain quantum conditions. Applied to the hydrogen atom, it is necessary, in order to make the motion degenerate, to assume that the Hamiltonian of this system is the same function of the dynamical variables as on the classical theory when expressed in Cartesian co-ordinates, but not when expressed in polar co-ordinates.—**C. S. Beals**:

Quartet terms in the arc spectrum of copper A series of observations of the magnetic resolutions shown by copper arc lines has led to the identification, in the spectrum of copper, of a number of quartet terms. The combinations between the quartet terms give rise to a number of multiplets, and combinations also occur between some of the quartet terms and the previously determined doublet levels. This is the first instance of the spectrum of an element of the first group of the periodic table containing terms of multiplicity higher than 2. It is thus an exception to the general rule, that the maximum multiplicity of the terms in the spectrum of an element is 1 greater than the group number of the element in the periodic table. It also raises the question as to whether the previously held ideas concerning the atomic structure of copper are correct.—J. H. **Brinkworth**: The ratios of the specific heats of nitrogen at atmospheric pressure and at temperatures between 10° C. and – 183° C. The ratios of the specific heats are calculated from experimental measurements of the cooling effect in adiabatic expansion. By combining the results of experiments by Dixon, Campbell and Parker, on nitrogen at high temperatures, with Callendar's theoretical expression for the variation in the specific heats, values of these quantities at any temperature and pressure may be calculated.—W. R. **Dean**: The elastic stability of a corrugated plate. The elastic stability of a shallow corrugated plate under thrust along its generators is considered. The depth of a bay of the plate is assumed to be a small multiple of the semi-thickness of the plate; a formally correct solution of the equations of stability can then be found. The critical stress is determined from the vanishing of an infinite, but rapidly convergent, determinant When the ratios of depth of bay to semi-thickness are 5 and 10 respectively, critical stresses 30 and 130 times that of a plane plate of the same thickness and height can theoretically be obtained. The solution breaks down if the ratio of depth of bay to semi-thickness is too large, or if the corrugation is so rapid that the curvature is large. —E. **Newbery**: The controlling factors of transfer resistance The variations of transfer resistance due to condition of electrode surfaces and changes of current density have been investigated with copper, silver, gold, nickel, and platinum. Transfer resistance is made up of two parts: (1) The resistance of a film of gas over the electrode surface; (2) the resistance of a layer of partially exhausted electrolyte surrounding the electrode. It is almost independent of the chemical nature of the electrode, but is high with polished surfaces and low-current densities. At very high current densities it is very low, due to the increase of conductivity of the gas film, but is greatly affected by changes of concentration of the electrolyte. Overvoltage is essentially a chemical, transfer resistance a physical, phenomenon —R. L. **Smith-Rose** and R. H. **Barfield**: An investigation of wireless waves arriving from the upper atmosphere. Owing to the high conductivity of the earth, it was impracticable to distinguish between waves propagated horizontally along the earth's surface, and others which might arrive in a downward direction, after deflexion from the upper atmosphere. By repeating the experiments on shorter wave-lengths, these directional measurements made it possible to establish directly that, under certain conditions, a portion of the wireless waves arriving at a receiver comes from the upper atmosphere. Systematic experiments have demonstrated the arrival of wireless waves at night at angles of incidence from 13° to 34°, for a wave-length of 385 m. and a range of transmission of 77 miles. Assuming the simplest case of a wave symmetrically deflected from the upper atmosphere in its passage from transmitter to receiver, the height of the deflecting layer is about 88 km. Evidence was obtained during the experiments of the arrival of waves after two and three deflexions from such layer.

Royal Statistical Society, January 19.—R J. **Thompson**: The productivity of British and Danish farming Statistical comparison shows that the average output per 100 acres of agricultural land is more than 50 per cent. higher in Denmark than in Great Britain. As compared with Great Britain, Denmark carries a heavier head of stock in combination with a high arable area, and feeds this stock to a greater extent from her own soil, this is combined with higher yields. Costs of production in Denmark may be lower than in Great Britain owing to the co-operative purchase of feeding stuffs, etc., and to greater personal labour by the farmer, while Danish labour may be cheaper owing to longer hours and greater efficiency. The smaller size of the holdings (in Denmark some 56 per cent. of the cultivated area is in farms of between 37 and 128 acres, while in England and Wales some 53 per cent. of the area is in farms of 150 acres and upwards), combined with the psychological effect of ownership, is the primary source of the difference in the agricultural systems of the two countries.

Mineralogical Society, January 19.—C. E. **Tilley**: Some mineralogical transformations in crystalline schists. Attention is devoted to the pelite isochemical rock series with special reference to the mode of origin of the index minerals biotite, almandine, staurolite, etc., in crystalline schists. A fuller recognition of the element of progression in metamorphism brings inevitably in its train this genetic problem, hitherto greatly neglected. Mineral and rock analyses are graphically represented in triangular plots. Examination shows that the mechanism of the mineralogical transformations is something much more complex than is explained away by the customary simple equations. Further insight into the prevailing reactions depends very largely on a closer chemical investigation of these common metamorphic minerals occurring in the ground-mass of the crystalline schists.—A. **Brammall**: Primary gold and silver in the Dartmoor granite. Occurrences of minute flakes of native gold in the normal grey biotite-granite were shown to be independent of quartz-veins, tourmaline veins, and zones affected by pneumatolysis, and flakes occur as inclusions in felspar and quartz. A suite of assays of apparently barren tor- and quarry-granites, graphic granite, pegmatites, and vein pyrites shows that both gold and silver are widely distributed throughout the granite, the values ranging from 1-10 grains of gold and 1-161 grains of silver to the ton. A sample of biotite yielded 108 grains of silver to the ton. Both metals are undoubtedly primary.—A. F. **Hallimond**: On the chemical classification of the mica group. (ii.) The basic micas. In continuation of previous work on muscovite, the analyses of biotite and phlogopite are recalculated in molecular proportions, SiO_2 being made equal to 600. The ratio of potash is approximately constant, as in the acid micas. Values for the R_2O_3 and RO groups are plotted in a diagram which makes it possible to compare any new analysis with existing data. On this diagram biotite and phlogopite form a continuous series, covering a very well-defined area and separated from muscovite by a wide interval. The representation of alumina in the form of basic groups, AlO, etc., leads to the classification of the micas in a range of increasing acidity from muscovite to phlogopite. This arrangement corresponds generally with the gradation in acidity of the rocks from which the respective micas were derived. The micas can be represented either by hexasilicic or trisilicic formulæ; evidence from certain phlogopites somewhat favours the latter type.—**G. Greenwood**: The construction and use of an X-ray goniometer. Crystal-structure of glyoxaline compounds. A new form of X-ray spectrometer has been constructed. It embodies the principles of the optical goniometer. The crystal is mounted on a goniometer head rotating about an upper scale, and the adjustments are made optically by means of a telescope and collimator. In using the apparatus, a source of X-rays is used instead of a source of light and an ionisation chamber instead of a telescope. The ionisation chamber rotates round a second scale, concentric with the upper crystal scale. Small and transparent crystals are generally used and it is then possible to measure the crystallographic angles, *i.e.* angles between crystal faces or lattice planes of the structure, and in this way to make the ordinary angle measurements even when the faces are not actually present. It is also possible to measure glancing angles and spacings, and thus to make determinations of the space-group to which the crystalline structure belongs. Two substances were investigated: (*a*) Glyoxaline-4-sulphonic acid. The space group was determined and the crystal class—previously determined from the alternating presence of minute faces—was confirmed. (*b*) Glyoxaline. This substance does not form complete crystals. It was possible to measure crystal angles, and deduce the axial ratios, etc. The symmetry is monoclinic.

Geological Society, January 20.—**T. O. Morris** and **W. G. Fearnsides**: The stratigraphy and structure of the Cambrian slate-belt of Nantlle (Carnarvonshire). The Nantlle Slate-Belt is the south-western part of the outcrop of the Cambrian rocks of northern Carnarvonshire, which rest with appreciable unconformity upon the late pre-Cambrian volcanic rocks running south-westwards from Llanberis. A succession has been established by the mapping, and is constant in all its divisions along the length and strike of the district. It is argued that the Lower Cambrian sediments are land-waste from the pre-Cambrian rocks of north-western Carnarvonshire and Anglesey, whereas the latter Middle and Upper Cambrian material was brought in from an unknown source away to the east and south. Ordovician sediments are faulted against the basal member of the Upper Cambrian. A buttress of Ordovician volcanic rocks flanks the Nantlle area on the south-east side; but, within the area mapped, there are only altered dolerite-dykes, later than most of the impressed structures, to represent (and that a very late stage in) the cycle of Ordovician-Devonian igneous activity. The Nantlle district was deeply involved in the making of the Devonian alpine range, the basal wreck of which is now Snowdonia, and all sedimentary material within the slate-belt was compelled to fold, and then to crush until, both in bulk and in detail, it began to shear and creep. Cleavage in the slate-belt is almost vertical. More boundaries of slate 'veins' and quarry properties are determined by slides than by bedding-planes. Between slides the slate-beds have characteristic anticlinal structures, the synclines being suppressed. With removal of load by denudation, joints and other tensional fractures have appeared. The latest cross-faults are master-fractures, which traverse all other structures as also the pre- and post-Cambrian formations that flank the slate-belt. The direction of these is north of north-west, as the geometry of the half-dozen which cross the quarry-region suggests that block-movement was associated with northward shift on the eastern side of each. Petrographic evidence establishes the existence of secondary (authigenic) micaceous minerals with or without recrystallised quartz in all the rocks of the slate-belt, and especially in those slates which are of greatest economic value.

Optical Society, January 21.—**R. Kingslake**: The interferometer patterns due to the primary aberrations. In order to obtain a rapid estimate of the quality of a lens by observing its behaviour in the interferometer, it is necessary for the observer to be familiar with the characteristic patterns of the various primary aberrations under various conditions of adjustment. These patterns are easily calculated for any required case.—**J. Guild**: (1) A trichromatic colorimeter suitable for standardisation work. The three working primaries of the instrument are obtained by means of filters. The mixing of the primary colours is effected by a periscopic prism which rotates past three stationary sectors. Provision is made for adding any of the primaries to the colour under test, where this may be necessary in order to obtain a match. In this way colours of higher saturation than it is possible to match directly may be dealt with. (2) A criticism of the monochromatic-plus-white method of colorimetry. From the practical point of view of quantitative colorimetry, hue and saturation are not the fundamental elements of colour quality but must be regarded merely as derivatives of the trichromatic constitution of the colour. Whatever may be the advantage of specifying colour quality by hue and saturation, there are grave objections to practical methods of colorimetry involving the direct measurement of saturation. (3) On a new method of colorimetry. A new method and instrument are described for determining the quality of a colour, as defined by its position on the trichromatic colour chart, in which only the colour-matching properties of the eye are involved. The determination depends on two colour-matches in each of which the test colour is matched by a mixture, in unknown proportions, of a standard colour and a monochromatic colour obtained spectroscopically, a different standard colour being used for the two matches.

Physical Society, January 22.—**T. H. Laby**: Critical discussion of the determinations of the mechanical equivalent of heat. The principal recorded determinations of the mechanical equivalent of heat are critically discussed, and an attempt is made to correct them for errors not fully taken into account at the time when they were made. The results are weighted according to the relative importance attached to them by the author, and the weighted mean is given as 4·184 joules per calorie at 20°.—**F. Ian G. Rawlins**: The present status of theory and experiment relating to specific heats and the chemical constant. Possible lines of advance have been indicated for solids in view of the progress now being made in X-ray crystallography; further experimental work on compressibilities and elastic constants is suggested. Tentative views on the specific heat of liquids are given. In gases the quantum theory of rotational heat fails to account satisfactorily for the behaviour of hydrogen at low temperatures. The chemical constant of monatomic and diatomic substances is discussed and current views on its nature are described. The theory of gaseous degeneracy and its bearing upon specific heats and chemical constants is reviewed.

PARIS.

Academy of Sciences, January 18.—**Paul Marchal**: The conditions of aerial or subterranean life of the Aphides, and in particular of *Eriosoma lanuginosum*.—**M. d'Ocagne**: The classification of all the methods of calculation derived from geometry and mechanics.—**E. Mathias**: Contribution to the study of the fulminating material. The energy per cubic centimetre and per gram at the moment of explosion. The theory of globular lightning.—**Charles Jordan**: New formulæ for comparing two probabilities *a posteriori*.—**Julius Wolff**: The iteration of limited functions.—**J. F. Ritt**: Meromorph functions which admit of a theorem of addition of multiplication.—**G. Valiron**: A theorem of M. P. Levy.—**A. Liénard**: A generalisation of the spherical vortex of Hill.—**André Samuel**: A new electrical insulator. The condensation product of formaldehyde with cresol is arrested at the viscous stage and this product treated with sulphur chloride. The substance thus obtained is named thiolite and can be polymerised by heating under pressure. The material has a resistivity of 300×10^6 megohms per cm. and a dielectric constant of 4·5.—**Gustave Bessière**: A method leading to the production of 'peristereoscopic' images.—**L. Vegard**: The interpretation of the spectra emitted by solid nitrogen and by solidified mixtures of nitrogen and inert gases.—**Pierre Bricout**: The production of ultra-violet light by the impact of electrons of low velocity on the surface of a metal. A detailed account of an experiment giving evidence in support of the emission of ultra-violet rays of wave-lengths between 2300 Å.U. and 2100 Å.U. as the result of the bombardment of a metal surface by electrons.—**P. Pascal**: The magnetic properties of the carbonyl radical. The diamagnetic exaltation produced by nitrogen is further accentuated when it is substituted by a negative radical, and is clearly attenuated when it is substituted by a positive radical. From this it follows that compounds containing doubly linked oxygen are no longer inexplicable anomalies in the laws of additivity of diamagnetism.—**B. Bogitch**: Iron-iron sulphide alloys. From the experiments described it is concluded that no iron-iron sulphide mixture, melted in the absence of foreign substances, gives rise to the formation of two liquid phases.—**Francis Perrin**: Determinations of the average life in the activated state of fluorescent molecules.—**Al. Favorsky** and **Mlle A. Tchilingaren**: The dehydration of the α-glycols. Molecular transpositions of ketones into ketones. Phenylisopropylketone is transformed into methylphenylacetone under the influence of zinc chloride.—**M. Bourguel** and **J. Yvon**: The synthesis of some *cis*-ethylenic compounds.—**P. Fallot** and **R. Bataller**: The tectonic of the southern border of the basin of the Ebre and of the mountains of the Mediterranean littoral between Tortosa and Castellon (Spain).—**G. Mouret** and **E. Raguin**: The prolongation to the west of the zone of dislocation of Boussac (Creuse).—— **Rey**: The collection of a mineral water by the method of reciprocal hydrostatic pressures.—**H. Buisson** and **C. Jausseran**: The ozone variations of the upper atmosphere. Spectrographic observations were made daily at Digne (height 600 metres) under good conditions of atmospheric purity between July 24 and September 29. The average amount of ozone, expressed as the thickness in centimetres of pure ozone at atmospheric pressure, was 0·3 cm., in agreement with earlier results. The extreme variation was about 15 per cent. from the mean. These changes cannot be connected with the atmospheric conditions. In particular, the local barometric pressure is without influence on the variation in the ozone.—**E. Tabesse**: Magnetic measurements in the Loire basin.—**Garsaux**, **Malassez** and **Toussaint**: Vertigo due to rotation.—**C. F. Muttelet**: A method for distinguishing preparations of 'regenerated' dried peas from preserved fresh peas.—**Jacques Benoit**: Histological studies of the right genital gland of the fowl ovariotomised into a testicle.—**Jean C. Faure**: The relative specificity of polyphage parasitic insects.—**G. Ramon** and **Ch. Zoeller**: The antigen value of the tetanus anatoxin in man. The injection of the tetanus anatoxin in man is absolutely innocuous. As a result of the injection, some tetanus antitoxin is produced in the blood, but the amount varies in different men. The possibility of immunisation against the tetanus infection is discussed.—**C. Levaditi**, **S. Nicolau**, and **I. A. Galloway**: The passage of the virus of foot-and-mouth disease through collodion membranes.

Diary of Societies.

SATURDAY, February 27.

North of England Institute of Mining and Mechanical Engineers (Associates and Students' Section) (at Neville Hall, Newcastle-upon-Tyne), at 3.—F. J. Johnston: The Use of Breathing Apparatus in Mines.—Paper open for Further Discussion—P. F. Hope: The Sinking of the Monkton Shaft.

Royal Institution of Great Britain, at 3.—Dr. G. Macdonald: Roman Britain (2).

MONDAY, March 1.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—Rev. B. N. Switzer: Some Biblical Discoveries relative to the Universe and its Origin.

Royal Institution of Great Britain, at 5.—General Meeting.

Society of Engineers (at Geological Society), at 5.30.—W. M. Beckett: Tidal Power on the River Severn—Some Notes and Suggestions on its Utilisation.

Institute of Transport (at Institution of Electrical Engineers), at 5.30.—H. D. Dickinson: State Ownership of Waterways.

Institution of Electrical Engineers (Western Centre) (at South Wales Institute of Engineers, Cardiff), at 6.—T. Carter: The Engineer: His Due and His Duty in Life.

Royal Institute of British Architects, at 8.—Lieut.-Col. H. W. G. Cole: The Paris Exhibition of 1925.

Aristotelian Society (at University of London Club), at 8.—G. D. H. Cole: Loyalties: A Study in Social Obligation.

Royal Society of Arts, at 8.—Dr. G. W. C. Kaye: The Production and Measurement of High Vacua (Cantor Lectures) (3).

Society of Chemical Industry (London Section) (jointly with Oil and Colour Chemists' Association) (at Chemical Society), at 8.—Prof. J. W. Hinchley, Dr. G. Martin, Dr. C. Beavis, C. A. Klein, and others: Discussion on Methods of Grinding.

Royal Society of Medicine, at 9.30.—Dr. G. Monod: From Cagliostro to Coué; or, Imagination as a Method of Treatment.

TUESDAY, March 2.

Royal Society of Arts (Dominions and Colonies Section), at 4.30.—Sir Basil Clarke: Publicity in relation to the Problems of Empire Settlement and Trade.

Royal College of Physicians of London, at 5.—Prof. W. W. C. Topley: Experimental Epidemiology (Milroy Lectures) (1).

Royal Institution of Great Britain, at 5.15.—Prof. J. Barcroft: The Egg (3). The Yolk.

Institute of Marine Engineers, at 6.30.—J. M. Lewis: Electrical Deck Machinery.

Institution of Electrical Engineers (East Midland Sub-Centre) (at Derby Technical College), at 6.45.—J. A. Aiton: Steam Pipes for Extra High Pressure and Temperature.

Institution of Automobile Engineers (at Royal Society of Arts), at 7.

Institution of Electrical Engineers (North-Western Centre) (at 17 Albert Square, Manchester), at 7.—J. L. Thompson and H. Walmsley: Notes on the Testing of Static Transformers.

Institute of Metals (Birmingham Local Section) (at Chamber of Commerce, Birmingham), at 7.—Dr. L. Aitchison: Light Alloys.

Royal Photographic Society (Pictorial Group), at 7.

Institution of Automobile Engineers (Coventry Graduates' Meeting) (at Broadgate Café, Coventry), at 7.15.—L. H. Dawtrey: Some Problems we Meet.

Institute of Metals (North-East Coast Local Section) (at Armstrong College, Newcastle-on-Tyne), at 7.30.—R. T. Rolfe: Bearing Metals.

Royal Anthropological Institute, at 8.15.—Mrs. J. B. M. McGovern: The Head Hunters of Formosa.

Röntgen Society (at Cancer Hospital), at 8.15.—Major C. E. S. Phillips: A Method of Increasing the Contrast of Shadows on Fluorescent Screens.

WEDNESDAY, March 3.

Royal Anthropological Institute (Edinburgh and the Lothians Branch) (at Royal Scottish Museum, Edinburgh), at 3.—R. Kerr: Demonstration on Recent Acquisitions in the Ethnographical Section of the Royal Scottish Museum.

Institution of Civil Engineers (Informal Meeting), at 6.—H. H. Lightfoot: Road Construction.

Institution of Electrical Engineers (Wireless Section), at 6.—R. A. Watson Watt: The Directional Recording of Atmospherics.—R. A. Watson Watt and J. F. Herd: An Instantaneous Direct Reading Radiogoniometer.

Institution of Heating and Ventilating Engineers (at Caxton Hall), at 7.—J. Meech: The Design and Application of Electric Motors relating to Heating and Ventilating Installations.

Institution of Automobile Engineers (Derby Graduates' Meeting) (at Cavendish Café, Derby), at 7.30.—L. A. Selvey: Permanent Mouldings and Die Castings.

Glasgow University Alchemists' Club (at Glasgow), at 7.30.—Prof. J. R. Currie: Iodine and Goitre.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.—H. Droop Richmond and J. A. Eggleston: The Analysis of Acetic Anhydride.—A. L. Bacharach: Notes on the Determination of Moisture, Calcium, and Phosphorus in the Bones of Rats.—Dr. B. S. Evans and S. G. Clarke: An Accurate Method for the Determination of Mercury in Solution.—Dr. B. S. Evans: An Apparatus for Continuous Percolation and for Filtration in Neutral Atmospheres.

Royal Society of Arts, at 8.—P. Dunsheath: Science in the Cable Industry.

Entomological Society of London, at 8.—B. N. Schwanwitsch: On the Evolution of the Wing Pattern in Butterflies.

Royal Society of Medicine (Surgery, Medicine, Electro-Therapeutics, and Therapeutics Sections), at 8.30.—Prof. Mellanby, Prof. Fraser, Mr. Dunhill, and Dr. Salmond: Discussion on The Treatment of Exophthalmic Goitre.

Royal Microscopical Society (Biological Section).

THURSDAY, March 4.

Royal Society, at 4.30.—Sir Ernest Rutherford and others: Discussion on The Electrical State of the Upper Atmosphere.

Linnean Society of London, at 5.—The President: Abnormal Specimen of *Typha latifolia*.—E. Heron-Allen: The Iconography of a Myth: The Barnacle Goose.—C. J. Stubblefield: Development of a Trilobite, *Shumardia*.—Dr. H. G. Cannon: Development of the Fairy Shrimp.—H. W. Pugsley: Revision of *Rupicapnos* and *Fumaria*.

Royal College of Physicians of London, at 5.—Prof. W. W. C. Topley: Experimental Epidemiology (Milroy Lectures) (2).

Royal Society of Medicine (Balneology and Climatology Section), at 5.15.—Dr. F. G. Crookshank: Airs, Waters, and Places.

Royal Institution of Great Britain, at 5.15.—Dr. C. D. Ellis: The Atom of Light and the Atom of Electricity (2).

Child-Study Society (at Royal Sanitary Institute), at 6.—Dr. P. B. Ballard and Mrs. B. Drake: The Curriculum for Children from 11 to 14 years.

Institution of Electrical Engineers, at 6.—R. B. Matthews: Electro-Farming; or the Application of Electricity to Agriculture.

Institution of Mechanical Engineers (Glasgow and West of Scotland Branch) (at Royal Technical College, Glasgow), at 7.30.—S. H. W. Dawson: The Oil Engine: Its Weaknesses and Advantages.

Institution of Structural Engineers, at 7.30.—S. Bylander: Steelwork Specifications.

Chemical Society, at 8.—S. Sugden and H. Williams: An Experimental Study of Protective Colloids. Part I. The Influence of Concentration.

FRIDAY, March 5.

Royal Society of Medicine (Laryngology Section), at 5.—W. M. Mollison and others: Discussion on Atrophic Rhinitis.

Society of Chemical Industry (Liverpool Section) (Annual Meeting) (at Liverpool University), at 6.—Prof. I. M. Heilbron: Recent Investigations on Fish Oils.

Society of Chemical Industry (Manchester Section) (jointly with Institution of Rubber Industry) (Manchester Section) (at 16 St. Mary's Parsonage, Manchester), at 7.—W. J. S. Naunton: The Accelerator Action of the Di- and Tri-Arylguanidines.

Royal Photographic Society (Pictorial Group) (Annual Meeting), at 7.—M. O. Dell: The Use of Filters and Panchromatic Plates in Landscape.

Photomicrographic Society (at 4 Fetter Lane), at 7.—E. A. Robins: Parasites.

Junior Institution of Engineers, at 7.30.—J. M. Seddon: Tendencies in Modern Electric Practice.

Junior Institution of Engineers (at Engineers' Club, Birmingham), at 7.30.—C. H. Woodfield: Hoisting Appliances.

North-East Coast Institution of Engineers and Shipbuilders (Middlesbrough Branch, Graduate Section) (at Middlesbrough), at 7.30.

Geologists' Association (at University College), at 7.30.—A. L. Leach: The Dolmen Region of South-Western Brittany (Lecture).

Royal Institution of Great Britain, at 9.—Sir Henry Maybury: London Traffic.

SATURDAY, March 6.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (1).

Gilbert White Fellowship (at 6 Queen Square, W.C.1), at 3.—Annual Conversazione.

PUBLIC LECTURES.

SATURDAY, February 27.

Horniman Museum (Forest Hill), at 3.30.—G. C. Robson: Squids, Cuttlefishes, and their Allies.

MONDAY, March 1.

University College Hospital Medical School, at 5.—Dr. R. A. O'Brien: Active and Passive Immunity. (Succeeding Lectures on March 5, 8, and 12.)

University College, at 5.15.—Prof. W. H. Lang: The Morphology of the Vascular Cryptogams in the Light of Pre-carboniferous Plants. (Succeeding Lectures on March 3 and 5.)

TUESDAY, March 2.

Middlesex Hospital Medical School, at 5.30.—Dr. G. Monod: Hygiene. (Succeeding Lectures on March 3 and 4.)

WEDNESDAY, March 3.

Imperial College of Science and Technology, at 5.30.—Prof. A. Sommerfeld: Atomistic Physics. (Succeeding Lectures on March 9 and 10.)

THURSDAY, March 4.

King's College, at 5.30.—C. J. Gadd: The Science of Divination (2).

SATURDAY, March 6.

Horniman Museum (Forest Hill), at 3.30.—Miss M. A. Murray: The Other World of the Ancient Egyptians.

SATURDAY, MARCH 6, 1926.

A British Science News Service.

UNDER the auspices of the British Association and the British Science Guild, a conference was recently held to consider the advisability of establishing a science news service in Great Britain, and after discussion a small committee was appointed to carry the matter further. For some time such a service has existed in the United States, and the success achieved in that country encourages the belief that there is room in British newspapers also for accurate information on scientific subjects, narrated in such a manner as to be interesting to the average educated but unscientific reader. Matter which is suitable for the American reader is not necessarily suitable for the British: each nation has its own idiom and its characteristic outlook. But what American science can do for America, British science should be able to do, in its own appropriate way, for Britain. Already the *Morning Post* and one or two other British papers make a feature of admirable reports on scientific subjects, while a few specially gifted men of science are doing excellent work by furnishing the press with informative articles: but apart from these exceptional cases it is a commonplace that the great majority of newspapers fail to distinguish between science and magic in anything but name, that the space they allot to science, as distinct from sensational charlatanism, is negligible, and that such paragraphs as they do devote to scientific topics are for the most part meaningless and in many cases untrue. The sporadic efforts of a few gifted journalists are not adequate to meet the situation. What is needed is a systematic supply of news the accuracy of which shall be guaranteed by recognised scientific organisations, while its form renders it easily digestible by at least the better educated newspaper readers.

It is a curious fact that while it is considered socially disgraceful to be entirely ignorant of literature, a man's conception of the material universe he lives in may be that of a primitive savage, without his thereby incurring the smallest social stigma. Yet it is of vital importance to a modern State that its people should appreciate the value not only of the past achievements of science but also of its current enterprises. In his recent presidential address to the British Electrical and Allied Industries Research Association, Mr. Ll. B. Atkinson dwelt on the fact that Great Britain, which can claim credit for the fundamental discoveries in almost all the principal branches of science, has little or no vision of what could be achieved for it, in the material sense, by the adequate encouragement of scientific research: only by the cumulative effect of reiterated reminders, in the form of scientific news items in the daily press, can the lay public be brought to recognise the untapped resources of command over Nature to which scientific research holds the key. The material advantages conferred by science are, however, to some minds its least valuable gifts. As a means of culture, as a perennial source of interest and wholesome enjoyment, scientific knowledge is a boon which the layman is entitled to share up to the limit of his mental capacity, and the specialist who makes discoveries is guilty of unsocial conduct if he fails to impart his good fortune, so far as is practicable, to the rest of the community to which he belongs. Moreover, if the results of research are of value, its methods are of far greater value. Scientific knowledge differs from unscientific in its quantitative character rather than in its essential nature. It is pursued more systematically, it depends on inferences which are more cautiously drawn, its propositions are held as having assigned degrees of probability rather than as being 'true,' it is characterised by more complete candour, and it is more resolutely guarded against the influence which habit and emotion exert on the judgment. Most of the administrative problems of the world could probably be solved by the application to them of similar standards of thought, and the more fully the general public comes to understand the methods of science, the better will it apply them in the conduct of its own affairs. The value of scientific method as an intellectual model and a mental discipline is at least as great as the value of its industrial achievements.

It must, of course, be recognised that scientific topics are not all equally suitable for popular consumption. The bulk of the matter to be supplied to the press would presumably consist of descriptive accounts of the results of research. Such subjects as the relation of animals and plants to man, or the phenomena observed during an eclipse, can with a little trouble be made interesting to readers of quite moderate education. Into the jam provided by such attractive items could be inserted, with tact and discretion, a reasonable proportion of pills in the shape of references to experimental methods (these would be of particular interest to skilled mechanics) and to reasoning processes. The rather disproportionate interest which the lay public takes in scientific hypotheses might also be gratified with safety, provided that the nature and use of a hypothesis be repeatedly explained. In all cases an attempt should be made to give the facts in true perspective, the relative degrees of probability attaching to various results being carefully distinguished, and the relation between observation and conclusion explained wherever possible.

There is already a keen demand for trustworthy information of the type described, and it is a demand which could be greatly increased by the provision of a suitable supply. Probably if there is one subject less suitable than the rest for popular exposition it is Einstein's theory of gravitation, yet when this was 'featured' by the *Times* some years ago, the public responded with a thirst for information which created an excellent market for popular books on the subject. If, then, the most esoteric subject that could possibly have been thought of met with such an enthusiastic popular reception, there can be no doubt as to the 'news value' of really suitable material. One or two of the higher grade of newspapers already find it worth while to provide accurate science news, and this fact, combined with the experience of the United States, indicates that a science news service need expect little difficulty in creating a market for its wares.

Doubt is sometimes expressed as to whether satisfactory popular exposition is seriously possible, and whether a scientific truth can ever pass into the mind of an unscientific reader without undergoing such distortion as to render it a fallacy. This objection might be sufficiently met by mentioning a few of the names which have made the Royal Institution famous, but the matter deserves somewhat closer attention. Newspaper readers are not a homogeneous class. Some will only be capable of following the simplest descriptive matter, but for the rest the improved teaching of science in schools is bringing into existence year by year a growing class of men who are quite familiar with the fundamental conceptions underlying modern science, and only need the stimulus of a daily news paragraph to enable them to resist the atrophy of their intellectual equipment.

Further, the difficulty of understanding scientific books and papers arises only in part from the intrinsic difficulty of their subject matter. It is beyond dispute that the published records of research are often extremely badly written. They abound in slovenly sentences giving rise to ambiguities which can be solved only by special knowledge on the part of the reader. They present ideas in a haphazard order which makes assimilation difficult. They omit to elucidate conceptions which are familiar to the author, but require explanation for the benefit of the less specialised reader. They fatigue the mind with the elaboration of minor details, and fail to focus attention on the really important parts of their subject matter.

The skilled scientific journalist, who mixes with the world in general sufficiently to understand his public, will avoid these faults. He will also know what to take for granted and what to explain, when to use a technical term and when to translate it. He will illustrate general principles by particular examples, and explain obscure conceptions by means of such analogies as are helpful and not misleading Above all, he will repeat his more important statements, varying their form and context, often enough to make sure of their being fairly grasped. Charles Darwin showed what can be done by a man who is himself clear-headed and takes the trouble to write simply, directly, and with a sympathetic regard for his reader's difficulties in comprehension. The "Origin of Species" consists largely of close and difficult reasoning, yet it is probably one of the most widely read and best appreciated books of its century. It should be the duty of any news service which may be instituted to provide day by day the kind of authentic yet digestible interpretation of science which such writers as Darwin have definitely shown to be attainable.

The committee which has been formed will be confronted with a number of difficult problems, which will have to be solved before success can be achieved. Perhaps one of the most difficult will be that of guarding the news against mutilation by unscientific sub-editors. On the other hand, there is little to be feared from the alleged hostility of the pioneer journalists who are already in the field. It is to the interest of all concerned to co-operate in creating an increased demand for science news, and it is therefore reasonable to hope that the parties in the case will agree to pool their assets, which are, on one side, experience and an established reputation, on the other, the prestige of scientific authority.

Without the willing assistance of scientific workers and institutions, no organisation for the preparation and distribution of science news can possibly be successful, and even with it, there is little hope that the agency would be self-supporting for several years. As regards finance, it may be mentioned that the American service pays for itself to the extent of about 60 per cent. of its expenses, the remaining 40 per cent. being provided by endowment. It has been estimated that a British service, selling news at standard rates, would need an endowment of at least 5000*l.* to ensure its being able to run for three years, at the end of which time it should be possible to decide whether the support secured was sufficient to justify the continuance of the service. One of the questions before the committee which has been set up is that of the possibility of raising this sum by contributions from public-spirited donors or other sources. It is unnecessary to discuss here the contrivance of machinery for obtaining and supplying news, but on the assumption that this and the other tasks confronting the committee can be successfully carried out, the scheme in its broad outline is one which must commend itself to every man of science who appreciates the significance of the discipline with which he is associated. C. W. H.

The University of London.

University Reform in London. By Thomas Lloyd Humberstone. Pp. 192+4 plates. (London: George Allen and Unwin, Ltd., n.d.) 7*s.* 6*d.* net.

THE signing of the Locarno Pact and the settlement of the Boundary question in Ireland can scarcely have failed to raise hopes in sanguine minds that, in such days as these, even the University of London difficulties may at last meet with some satisfactory solution. A Departmental Committee of the Board of Education, appointed in 1924, is at work. It is sitting behind closed doors, but it is understood that evidence has been taken and that before long we may have the Report. It is certain that when the Report does come, it will be read with the utmost interest and examined with the closest scrutiny by all who are interested in British university education.

With this prospect before us there comes to hand in the most timely way a book that will be invaluable in supplying to all who seek it a compact and readable account of the history of the University of London. Mr. Humberstone calls his book "University Reform in London," and he writes not merely as a chronicler but as one imbued with a zeal and a policy for reform. In such circumstances, it is not easy for a writer to present an undistorted tale of history, but, though the reviewer differs from Mr. Humberstone on a number of questions, he has no single word of complaint to make of prejudice or distortion. On the contrary, he is grateful for an historical summary that is at once accurate and alive, far removed in style from the monotonous correctitude of the civil service essays in which so much of our authentic educational history is—perhaps necessarily—enshrined. One is impressed but not oppressed by what Mr. Wells calls the high sincerity of the writer; he has a literary gift, a light touch, and an engaging frankness that greatly help the march of his story. Where he is adding his own comments or expressing his own views, it is plain to the reader, and it is quite refreshing to have here and there some serious proposal stigmatised as preposterous. The size of the book, the print, and the three aircraft plates of Bloomsbury, South Kensington, and King's College, are admirable.

For an adequate appreciation of Mr. Humberstone's outlook, the reader must be referred to the book itself; it must suffice to say here that he expresses strong opinions about the restoration of the Royal College of Science at South Kensington (the "Imperial College" being left for technology), and he is strongly in favour of full development of Bloomsbury as a university quarter. On the whole his counsels are those of moderation, and he seems quite hopeful of harmonious co-operation being achieved in the University without any subversive constitutional change.

The University of London is so complex, the individual knowledge and interests of those who criticise so varied and often so partial, that it appears less presumptuous to speak about it in the first person singular than to usurp an editorial "we," and in what follows that course will be taken.

I have had for nearly half a century a close interest in the University of London. As a student of chemistry at Owens College, Manchester, I became indebted to it as affording me the sole available means of obtaining a university degree. In early life I was thrown much among men with whom, in the days of religious tests at Oxford and Cambridge and the neglect of science there, the University of London stood for emancipation, freedom, and progress. It gave a university franchise to a vast section of the community suffering from a genuine grievance; it was subserving the development of the new universities that have arisen in our great cities; and it gave university privileges to women. It must be difficult for the younger generation to-day to understand the intensity of feeling which lay behind and still in a measure survives in the external examining service of the London University. People have wondered how, for example, Convocation can ever have claimed so great a say in the University affairs; but it is easy enough for Victorians to understand—whether they approve it or not.

During the modern period of university development, the new universities in the provinces have, of course, been watching one another very closely, but they have been watching, not less closely, the University of London. What London does matters very much to them. There are two chief reasons for this. In the first place London seems from a distance to stand in more danger than any other university of coming into the toils of Government and bureaucratic control. In the second place, there is the possibility of London having ascribed to it duties or privileges of a metropolitanism and even an imperialism for its University, because London is the capital of England and the chief city of the Empire.

Of these questions I will only refer to the first, and on that little need be said in the columns of NATURE, for most of its readers will know how deep and intense in the English university world is the feeling that freedom and autonomy are beyond all else vital to a true university. They know that the possible encroachments of Government or other bureaucratic authority on university preserves even in England have called for constant vigilance. They know also the peculiar position the University of London has occupied in relation to the Government—or if they do not they will learn it from Mr. Humberstone's book.

Apart from the two special questions that I have named, there has naturally been great interest among those engaged in the newer universities in watching the efforts that have been made in London to achieve the stupendous task of welding into a genuine university the array of varied institutions which were providing studies of the university type. As a problem of organisation and administration, it is unique in magnitude and complexity, and in the purely educational aspect it is fraught with complications and difficulties of a quite peculiar kind. A smooth course of construction, a rapid achievement of unity, could not be expected by any reasonable person.

The University of London is bound, *ipso facto*, to be great in one sense, and it may easily be made great in external appearance by the aggregation of buildings and the creation of an imposing University quarter. But of course the real difficulty is to supply not the body but the soul to a University of London. We can conceive what might have been now if there had been in early times a true University of London, and if this University, growing up *pari passu* with the growth of London itself, had become scattered into such discrete and distant parts as those now comprised within the University. The parts would have had a genetic relationship, and there might well have been preserved among them, even within this modern community of more than ten million people, a reality and sense of University fellowship, a pride strengthened by time and tradition in being members of a great learned and humanising corporation in the metropolis of the Empire. We may conceive that in its specialist institutes and single schools, in its social amenities of clubs and parks, there might have been strong agencies for promoting a collective university spirit. But the University, even if in substance and action little more than a name, might have remained an august and genuine *Alma Mater*.

To bring together the constituent parts, as they were at the inception of what is known as the teaching University of London, and to imbue them instantly with any of the spirit which has just been referred to, was certainly not to be expected. I confess to having considered the problem to be well-nigh hopeless and to have been inclined to think that the most likely solution of the University question in London would lie in the creation of several completely independent universities. This state of mind arose from my experiences and instincts as a university teacher and the apprehension I felt in observing how strong seemed the faith in some minds that a University of London was to be created by mere aggregation—by catching and binding institutes and teachers into an examinational nexus, and by creating a machinery of organisation, co-ordination, and administration that together promised to make the life of a university teacher in London scarcely worth living.

I am happy to say that recent events have modified my opinion. The decision of King's College to remain where it is and to abide by limitations of space and numbers whilst making itself as good as it can be, was announced in June last in the *Times* by a letter from the Principal, Dr. Ernest Barker, which rang with a clear and arresting note. The Imperial College, under its new Rector, Sir Thomas Holland, has also apparently by a shrewd stroke reached a condition of contented life within the University circle. This trend of opinion and action seems to give good hope for the future. I am one of those who believe that a strong individual life of colleges must, in London as in Oxford and Cambridge, underlie any real strength of the university, and that it will be in keeping the official bonds within the university as light as possible that we may hope to see them grow strong. The *Lehrfreiheit*, of which perhaps we are rather tired of hearing, is after all a very serious aspiration, and equally serious are the susceptibilities of important public men, who give time and labour voluntarily to the management of individual colleges.

I believe that here, as in so many other corners of our educational world, the root of trouble is to be found in the false attributes which have been put upon university degrees. The apprehension that the freedom of a college will be associated with a laxity of academic standards is of course the natural view of the man in the street, but it is still felt also to some extent within the teaching world itself. People seem to forget how wide and influential an educated public opinion has arisen in the course of the last generation. It is perhaps more difficult in London than elsewhere to realise what an array of educational officials, what multitudes of headmasters and other teachers trained in the modern universities, are now watching all the universities and colleges, and how quick and effective is their detection of any shortcomings. Not much is said aloud, but there is a closeness of scrutiny and a silent appraisement in existence that make little of examination syllabuses or lists and go right to the heart of things. I am certain that the new universities in the provinces are sensible to-day of an intelligent and mute surveillance which is constantly and justly estimating their sterling value and letting it be known wherever such knowledge matters. I believe that the danger of London colleges under-bidding one another in their courses for a degree need in these days cause no anxiety. The question that will more and more be asked of London graduates will be, as it now is with the initiated, not whether they have an honours degree, but how, where, and by whom they were trained.

It was my fate to work for seventeen years in the bonds of a federal university wherein three colleges were acting together, linked closely in a degree system intended to preserve a uniform academic standard and a just classification of graduates. The condition was of course a great improvement on that of wholly external examination, and no doubt the teachers of the different colleges gained a good deal from intercourse and discussion in Boards of Studies and in their joint examining. But many of us felt the restrictions to be very serious, and in the following years of liberty the University of Leeds, and I think it is equally true of Manchester and Liverpool, has worked to more valid and really higher standards and has dispensed its honours with much greater justice. I see no reason why the disbanded colleges might not have obtained much, if not all, of this freedom and still have remained in name members of a Victoria University if there had been any strong practical or sentimental motive for such a union. But the case is of course different with the colleges and institutions in London. Here, there are both an obvious and compelling argument for inclusion under one university name and the geographical possibility of collective university action in the creation of special institutes and in bringing into common account the great and unique treasury of resources which London can contribute to university studies. The prospects for the teaching University of London appear to me to-day to have grown very sensibly brighter.

For the externally examining agency I can see a useful place if it be disentangled from the teaching university. Until the provision of universities in the country is completed, there will still be some developing colleges seeking the mark of a degree for qualified students. They had surely far better come to London, as of old, instead of trying to stir the new universities in the provinces to begin upon the work in which London is so well practised. Besides this there are, no doubt, and may be for a considerable time, a good many individual hard cases that are met by the externally examining system. But there is one thing that even the most devoted of the old guard of the external side of the University of London must now recognise; it is that the strength of opinion which has been steadily growing against completely external examining from top to bottom of our educational system, is now overwhelming, and that the external degree of London cannot escape the consequences.

The short preface which Mr. Wells contributes to

Mr. Humberstone's book is written in a vein of striking earnestness. Mr. Wells is of course one of the most distinguished beneficiaries of the old examining agency that bore the device of a university. The outlook which he now takes is, I think, very much the same as is taken in this article. If all of us who owe so much to the system that had its day and is ceasing to be, can readjust our loyalty as fairly as Mr. Wells has done to the system that must now succeed it, we should be doing a great good turn for a true University of London.

A. SMITHELLS.

Industrial Distillation.

Principles and Practice of Industrial Distillation. By E. Hausbrand. Translated from the fourth, new and enlarged, German edition by Dr. E. Howard Tripp. Pp. xx + 300. (London: Chapman and Hall, Ltd., 1925.) 21*s.* net.

THIS translation of Hausbrand's "Die Wirkungweise der Rektifier und Destillier Apparate" is a welcome addition to the comparatively small number of text-books on distillation which are available in the English language. As the original work has attained the rank of a standard treatise in the country of its origin, where it has reached the fourth edition, and as it is well known in other countries to those who can read German, it is rather surprising that a translation has not been attempted before now. As publication, however, although delayed, supplies an obvious want, there is no doubt that the book will find its way into the hands of many readers to whom it should prove of great service and interest.

Hausbrand's analysis of the various processes which occur in the distillation apparatus has the peculiar merit of avoiding any use of the calculus, and in this respect his presentation of the subject will appeal especially to those readers who are confounded by the integration which is so frequently employed by other writers. On the other hand his methods, although easily understood by the non-mathematical student, would appear to involve a great number of calculations. It is true that the results of such calculations for eleven of the best known mixtures are given in tabular form with great detail and for a variety of conditions such as are met with in practice, yet for other pairs of liquids than these, the necessary work would be both tedious and time-consuming compared with that required in the graphical integration which is such an important feature in other methods of analysis. Throughout by far the greater part of the book, the author has very wisely employed percentages by weight instead of the molecular percentages so much beloved of other writers. In the small section devoted to the calculations of the vapour composition curve, molecular fractions and percentages are employed quite correctly because they are essential, but their introduction into any analysis which purports to be of a more or less practical nature is not only confusing but also in the majority of cases quite unnecessary.

The extensive tables and accompanying graphs which form such an important feature in the book are very instructive when studied in connexion with the text. It must, however, be remembered that, as with all other methods of analysing distillation processes, it is necessary to assume that equilibrium conditions hold between a mixture and its evolved vapours. As such conditions do not exist in the working column, it is necessary to apply a correcting factor to the results obtained by using either Hausbrand's or any other method. This does not detract in any way from the great value of the book to all those engaged in practical or academic work connected with distillation. It does point to the need of establishing the relationship between the number of plates in a perfect and in a working column for different values of the reflux ratio and different initial and final concentrations of the mixture to be distilled.

There are some parts of the book where the author has preferred to calculate tables by first evolving somewhat fearsome formulæ, whereas a simple example would have saved time and trouble. For example, to arrive at the alcohol content of the residual liquid (Section 11, pp. 36 *et seq.*) several pages are devoted to evolving two equations by which the data given in Table 4 are calculated. The necessary calculations are, however, so brief and simple that the section seems redundant or, at least, could be severely compressed and explained by one example occupying a few lines. In some other directions similar remarks might be made. Viewed as a whole, the work is of considerable practical utility and contains a wealth of information which can be studied with advantage in connexion with plant on the works scale. In the first part of the book the underlying principles are explained, and in the second part is given the application of these fundamentals to the calculations of the required dimensions of fractionating columns. The work is a classic which has found great honour in its own country. In its English version it should be read by all those interested in the subject of distillation.

The translator, while remaining faithful to the sense of the original, has succeeded in his object of producing an English work free from the style and the long involved construction which are so peculiarly German and must considerably perplex those who are imperfectly acquainted with the language. The reviewer, having read the original, can appreciate the excellent way in which the lengthy periods so common in German scientific and technical literature have been rendered into easy flowing English. The original work contained a great number of mistakes especially amongst the suffixes, but these have been carefully corrected. In the translation very few are to be found and none of importance; 0·35 instead of 9·35 in Table 4 would not lead any reader astray. On p. 12 on the bottom lines, "must rise with" would be more correctly translated as "must rise within" (*innerhalb*) or "as part of." All such criticisms are, however, of very slight weight. Printing, binding, etc., are excellent, and improvements on the original.

C. ELLIOTT.

Biology of Cancer.

Tumors and Cancers: a Biological Study. By Hastings Gilford. Pp. xii + 703. (London: Selwyn and Blount, Ltd., 1925.) 42*s.* net.

MR. HASTINGS GILFORD has approached his subject as a biological study, a point of view which has received comparatively little attention from those engaged in cancer research. In a very exhaustive survey, the author discusses the natural history of tumours and their relation to normal and abnormal growth and development. Development is considered as a cyclical movement, a progression followed by regression, and Mr. Gilford believes that cancer ensues when certain cells complete their developmental cycle prematurely and are roused into regressive activity by stimuli; it is thus essentially of intrinsic production and a disorder of development.

It is a little unfortunate that this book was published before the description by Gye and Barnard of their recent work in cancer research, to which at first sight Mr. Gilford appears to be in direct opposition. Had the book appeared a year later, more consideration might have been given to the possibility that micro-organisms could play a part in stimulating cells into regressive activity. In all diseases which are due, or probably due, to bacteria, there are two factors to be considered: they are the causal microbe and the relative immunity of the body. Lack of methods for better understanding of the latter has driven research in infective diseases into search for and study of the nature of the microbe, and it is only recently that predisposing causes have begun to be thoroughly investigated.

To some extent Mr. Gilford's book provides a review of the predisposing causes of cancer, and so far he is not at variance with other workers on the problem. Where he definitely departs from the trend of modern research is in considering the real source of cancer as essentially intrinsic. Tuberculosis is just as much a reaction of the body as is cancer, though we now know it to have an external cause, which, however, is negligible if the body is completely immune. The problem of cancer will not be solved until there is full understanding of the exciting causes as well as of the steps by which healthy cells change to form a malignant colony.

Mr. Gilford's view of cancer as essentially a developmental error leads him through an interesting survey of the sins of personal and racial life which predispose to such error. Thus he sees at the root of malignant disease our national state of "accelerated or premature senescence," and associates it with a spirit of diffidence and indifference in facing our social problems. While the cure of our political ailments and the removal of our personal errors of living may not eradicate cancer, nobody will fail to agree with him in his plea for a better form of civilisation and conformity to the rules which promote a higher standard of individual and national health.

Our Bookshelf.

Practical Physical and Colloid Chemistry: for Students of Medicine and Biology. By Prof. Leonor Michaelis. Authorised Translation from the second German edition by T. R. Parsons. Pp. x + 195. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1925.) 7*s.* 6*d.* net.

THE English translation of this very useful book is to be cordially welcomed. Although it is intended for students of medicine and biology, and many of the examples in it are selected accordingly, the student of general colloid chemistry will derive considerable benefit from working through the greater number of the exercises. The very first chapter gives a much clearer account of the principles of serial experiments—which play so important a part in the study of electrolyte coagulation and of adsorption—than is to be found in the existing laboratory manuals. The application of these principles is thoroughly illustrated in the subsequent exercises on electrolyte coagulation and on the Hofmeister series. The author, in common with all European authors, appears to be quite convinced of the reality of the anion effect, in spite of J. Loeb's criticisms, and, following Wo. Ostwald's example, demonstrates it with hæmoglobin instead of the usual egg or serum albumin. The chapters on the determination of hydrogen ion concentrations are excellent, and a student who has mastered the one entitled "Units and nomenclature" ought to have no illusions on the accuracy of statements like "*p*H 4·3 to 4·6," and should be able to state either offhand in gram-ions per litre. Viscosity is treated somewhat briefly, and some exercises on sols other than that of gelatin would have been instructive. On the other hand, the sections on surface activity and on adsorption—on which subjects the author has done much original work—contain a number of very ingenious experiments not to be found in other manuals.

The translation is unusually good, and it is a pleasure to read an English rendering of a German text in which no hyphenated nouns and compound adjectives have been allowed to intrude. The translator might, however, have considered it part of his functions to restore a victim of the German mania for phonetic spelling like "Tindall" to its correct form, and even in these degenerate days he should have given the participle of *adjuvare* its proper termination instead of making it "adjuvent."

Principles of Genetics: an Elementary Text, with Problems. By Prof. Edmund W. Sinnott and L. C. Dunn. (McGraw-Hill Publications in the Agricultural and Botanical Sciences.) Pp. xviii+431. (New York: McGraw-Hill Book Co. Inc., London: McGraw-Hill Publishing Co. Ltd., 1925.) 17*s.* 6*d.* net.

THIS book is intended to be used by first-year students taking an introductory course in genetics, and appears to be well adapted for the purpose. It is pleasantly and clearly written, the numerous illustrations are well executed, and the authors have succeeded in obtaining a fair proportion which are not already over familiar. An innovation in this class of book is the introduction at the end of each chapter of a number of "Questions for Discussion," of "Problems," and of what are termed "Reference Assignments." Of these, the problems are on the whole excellent, and, to the student who conscientiously works through them, should provide a good test as to whether he has fully grasped the subject matter on which they are set. They should also prove useful to the teacher. The reference assignments are perhaps intended for more advanced students, for many of them seem too difficult for elementary ones.

If, as is likely, a second edition of the book is called for, the authors should pay a little more attention to their historical sketch, and to the crude diagram on p. 6. Genetics is here shown emerging from the "Dark Ages" with the discovery of spermatozoa by Hamm in 1677, as though the names of Harvey and de Graaf had no significance for students of this science. Nor was the function of the sperm discovered by Spallanzani about 1700, for at that time he was not even born. To Camerarius too should be given some credit in the discovery of the process of fertilisation in plants. And why should not Buffon and Erasmus Darwin be mentioned in connexion with theories of evolution? The dates after some of the names evidently refer to a famous publication such as Darwin, 1859, Mendel, 1865; but why should 1779 be assigned to Knight, who was then a young man of twenty years with nothing particular to his credit? We agree that a brief historical sketch might well be both interesting and illuminating, but to be of any real service, it must be more accurate and more comprehensive than what is given here.

Graphical Methods of Plotting from Air Photographs. By Lieut.-Col. L. N. F. I. King. Pp. 92. (London: H.M. Stationery Office, 1925.) 3*s.* net.

THE rapid development of aerial navigation has opened the door to a number of new subsidiary possibilities, not the least of which is the mapping and surveying of large areas from air photographs. Generally speaking, the problem is twofold. It is concerned in the first place with the scientific conditions under which the photographs are to be taken and the scientific machinery, camera, lens, plates, etc., for effecting this. In the second place, it is concerned with the principles and methods that have to be devised for the accurate interpretation of these photographs in terms of an exact geometry of the landscape. The present collection of notes deals with the second aspect of the question, not as a dogmatic treatise on the subject—it is too early for that—but as a record of graphical processes that may be utilised in the analysis and synthesis of such photographs and the geometrical principles upon which such processes depend. It is not claimed that for this purpose graphical methods are necessarily superior to other possible methods of a mechanical or a photographic nature, but that many cases must occur both in peace and war where individual and tilted photographs must be made to yield their secrets, and the graphical processes described in this work will do it.

There are many parts of this interesting subject that might with advantage be incorporated into a course on perspective and descriptive geometry, and teachers of this subject would do well to examine this little book. One word of criticism. One does not require to be a purist to object to the word "photo," especially when it alternates with "photograph," so that no new significance is attached to it. Its frequent appearance on every page of this Government publication does not convert it into the King's English.

Chemistry to the Time of Dalton. By E. J. Holmyard. (Chapters in the History of Science, 3.) (The World's Manuals.) Pp. 128. (London: Oxford University Press, 1925.) 2*s.* 6*d.* net.

To the majority, perhaps the vast majority, of trained chemists, the history of their subject is practically a closed book, partly because they lack the historical sense, but also because they have been repelled by the manner in which the subject has been presented. To write a readable history of chemistry that will appeal to the practically-minded is no easy task; alchemy, with its lure of gold, has always a certain fascination, but the symbolical writings of its devotees are painfully dull to all except the specialist; and the long-drawn-out controversies of later times on views that are now held to be mainly erroneous are no less wearisome. To those who have passed through the mill, or have been arrested at its threshold, Mr. Holmyard's little book will be heartily welcomed as a successful attempt to present in bold outline a history of the development of ideas which have played a great part in the elaboration of modern chemistry, notably those on the constitution of matter and on the nature of combustion; and the author's original work on the gropings of the early Muslims will add a spice of novelty to what is usually regarded as dull and indigestible. Specialists will naturally ask for a more detailed treatment than that here presented, but they also will read with pleasure and profit this valuable introduction to the subject. The book is well written, profusely illustrated, and remarkably cheap.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Loculus of Archimedes.

IN the course of study, of a totally different subject, I recently came across reference to a pastime of the ancient Greeks and Romans, which was of the same nature as the Chinese puzzle, or Tangram, though more elaborate. Curiosity being excited, the scattered references were hunted up, and it was found possible to reconstruct this puzzle with practical certainty, though I have not been able to discover that this has previously been done. From the manner in which this has been received, by those who have seen it, the subject appears to be of sufficient general interest for the result to be placed on record.

To this puzzle the Romans applied the name of *loculus Archimedius*, the first word meaning a small receptacle divided into compartments, the second referring to the name of the reputed inventor. The Greek name is uncertain; the lexicons give it as *ostomachia*, but the only authority quoted is the Latin writer, Ausonius, and this is the form usually adopted by the editors of the printed texts, though the word is sometimes given as *stomachia*. The question of the choice between these two forms was discussed at length by Prof. J. L. Heiberg, in 1907 (Hermes, *Zeitsch. f. class. Philol.*, 12, p. 240), who concluded that the first named, usual, form is a mistaken emendation of the editors, and that the other is the correct one; it is also the form found in a palimpsest, deciphered by him in 1906, and the only known occurrence of the word in a Greek manuscript. If ostomachia is correct the interpretation would be a battle or struggle of bones, while stomachia, or stomachion, would mean the thing that drives one wild.

The descriptions of the Latin writers, being in each case a parenthesis, in illustration of a very different subject, are naturally incomplete, but they show that the puzzle consisted of fourteen pieces of ebony or ivory, mostly in the form of triangles of various kinds and descriptions, with some pieces of a larger number of sides, which were combined to form pictures of fearsome elephants and barking dogs, of ships, castles, and many other objects, but, adds Ausonius, though the compositions of the skilled are wonderful, the efforts of the novice are ridiculous. To this all that can be added is that the whole set was contained in a *forma quadrata*, an expression which, like its English equivalent, square, in geometry implies equality of the four sides, but, in literary or colloquial language, need mean no more than a rectangle.

These descriptions, though they give a good general idea of the puzzle, are no help to a reconstruction of it; of this the first information became generally available in the publication, by H. Suter, of the text and translation of two Arabic manuscripts, preserved in Berlin (*Abh. z. Geschichte d. Mathematik*, 9, 1899, pp. 493-499). The Arabic text is itself a translation from the Greek and is entitled the book of Archimedes on the division of the Stomachion into fourteen parts; it contains a description of the construction, followed by a demonstration of the relation of the area of each separate part to the whole. The translation is illustrated by a figure, reproduced in Fig. 1, which appears to be a reconstruction by the translator, as no mention is made of any figure appearing in the manuscript, and two similar manuscripts, in the India Office and Bodleian libraries, are both wanting in the figure, for which a space is left. The construction may be briefly described: the figure ABGD, drawn as a square but described in the Arabic as a parallelogram, is divided into two equal parts by the line EZ, parallel to AB; the diagonals AG, BZ, ZG are drawn; AL is bisected in M, and BM joined; BE is bisected in H, from which HT is drawn parallel to AB, and HK as part of the line joining HA; ZG is bisected in C, and DG in N, and EC, CN are drawn; finally CO is drawn in continuation of BC; the whole figure being thus divided into fourteen parts.

This interpretation appears to have been accepted by scholars as a representation of the loculus, but an examination throws doubt on this conclusion. First there is the practical difficulty that it gives a number of very acute angles, which would not only need skilled and careful workmanship to produce, but the razor edges resulting, in one only just over 11°, would be too brittle to stand usage, and would rapidly become damaged. Secondly, a comparison of the translation with the Arabic text shows that while, in the former, the outer figure AG is described as a square, and the two halves AE, ED as rectangles, the latter consistently uses the same word, which means no more than a parallelogram; and in this the Arabic is logically correct, for it treats the subject as an exercise in pure geometry, and the construction, together with the subsequent discussion, is equally applicable to any parallelogram, irrespective of the magnitude of the sides or angles.

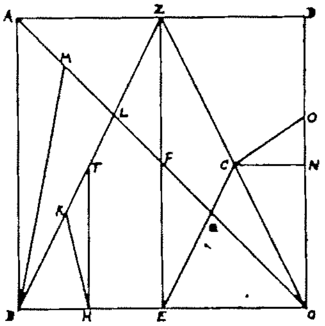

FIG. 1.

These doubts have been largely cleared up by the discovery, in 1906, by Prof. J. L. Heiberg, of Copenhagen, that a palimpsest, preserved in Constantinople, was overwritten on a copy of the works of Archimedes, which has not only yielded very important additions to the previously known body of his writings, but also contains, at the end, part of a book of the Stomachion, the existence of which had been unknown. This fragment was first published in 1913, in the second edition of the works of Archimedes, edited by Prof. Heiberg for the Teubner Classical Library (vol. 2, p. 416 ff.). The opening paragraph of this fragment says that as the thing called the Stomachion presents examples of the method of transposition of figures, he thinks it well to treat of these and to show how it is divided and how the parts resemble each other, so that, in forming them into pictures, one may see how the angles may be combined to form two right angles, and whether two sides, which appear to lie in a straight line, do so, or depart slightly from it; though a picture is not necessarily to be rejected on account of a small gap resulting from this. It is evident from this summary that the complete book would have made a very interesting treatise on the game, but only two short passages remain. The first, following immediately on the introduction, demonstrates that the angle AMB (Fig. 2) must be an obtuse one, and the second, following on a gap, is part of the description of a construction, similar, so far as it goes, to that

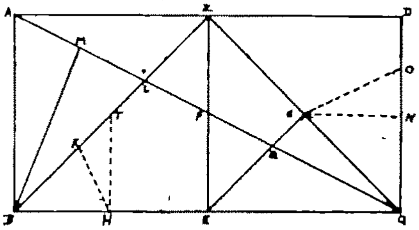

FIG. 2.

described in the Arabic manuscript, with the instructive addition that, after the first division of the whole figure into two equal halves, each half is a square.

From these passages two conclusions may be drawn: that the pastime was really an invention of Archimedes, and not merely fathered on him, and that the initial figure of the loculus was not a square, but a rectangle composed of two squares, set side by side. This makes it possible to reconstruct the pattern of the divisions, as shown in Fig. 2, where the firm lines show the construction, so far as the text of the palimpsest goes, and the dotted lines the completion, taken from the Arabic text. I have, however, made one departure from the Arabic, in drawing the triangle OCN, which appears necessary if the thing is to be used in the manner described, and not as a mere exercise in geometry.

If Fig. 2 is examined it will be seen that the angles are either right angles, or the angles made by the diagonal of a square, or those made by the diagonal of a rectangle twice as long as it is broad, or the sum or difference of some two of these, so that there are many possible combinations by which either two or four right angles can be built up. Also, for length of side, we have the whole, half or quarter of AB, the half, third or sixth of BZ, and the third or sixth of AG, so that there are a number of sides which can be matched with each other, either singly or in combination. To this there are two exceptions: the line BM cannot be matched with any other side or combination of sides, nor can the angles at B and M be matched with any others to complete either two or four right angles, but the other sides of the two triangles, based on this line, and the angle between them can readily be matched, as can the combined triangle ABL. The other exception is the triangle OCN, and this is a very different case; if drawn according to the Arabic construction, with CO as a continuation of BC, it would have the angles of the diagonal of a rectangle of sides three by one, and the common side CO, the two sides NO, OD, and the four angles at O and C would none of them be matched with any other sides or angles. If, however, DN is bisected in O, we have a construction more in tenor with the rest, and get a triangle with angles of the diagonal of a two by one rectangle, though the length of the side CO, being one quarter of AG, would still be impossible to match with any other side. For these reasons it seems probable that, whatever may have been the original construction, designed as an exercise in geometry, the modification would soon have been introduced when it was adopted as a pastime, for, so far as may be judged from a slight experience, it is a marked improvement.

However this may be, it seems clear that, with this possible, though not probable, exception, we have, in Fig. 2, the actual pattern of the pieces forming the loculus mentioned in Latin literature. As examples of what can be done with it I may give a few ridiculous efforts of a novice (Fig. 3); the elephant (i), the ship (ii) and the two figure studies, which I owe to Sir Richard Paget, of the Pied Piper (iii) and the Pundit (iv) will give some indication of the wide range of subjects which can be depicted, in a somewhat cubist style it is true. The last-named figure, it may be noticed, contains one of those small gaps, which, the palimpsest expressly declares, need not involve the rejection of the figure. In each case the whole fourteen pieces are employed, this being, presumably, of the essence of the game; it happens at times that a satisfactory figure may be built up, with one or two pieces to spare, and then the fitting in of these superfluous pieces becomes the thing that drives one wild.

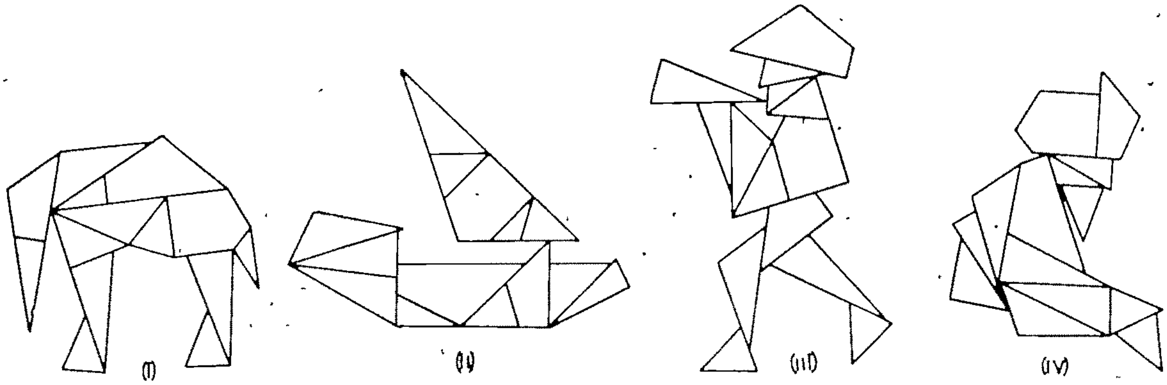

FIG. 3.

R. D. OLDHAM.

Use of an Artificial Horizon in Photographic Measurements of Buildings or other Structures.

IT is sometimes required to know whether certain lines intended to be vertical or horizontal in buildings or other structures are really so, and if not, by how much they deviate from these directions. All such measures can, of course, be made by a theodolite or level, but when many details have to be examined this is a long process.

A photographic method, however, which I made use of during the construction of the Tower Bridge, and elsewhere, compresses in a few negatives information which it would take weeks to acquire by direct instrumental observation on the spot.

This method, which I have had occasion to use again recently, consists in photographing the object to be measured, together with its image in an artificial horizon. If the lens used is free from spherical aberration and the plates are suitable, each negative will yield all the information which could be obtained from a theodolite of the same focal length.

Collodion plates give the best results. In all gelatine emulsion plates the coarseness of the grain is against the use of high power in the analysis of the image, and the more sensitive the plate the coarser the grain.

If a_1 a_2, etc., are points in the direct image and a'_1 a'_2, etc., corresponding points in the reflection, then straight lines joining a_1 a'_1, a_2 a'_2 are true verticals, and the straight line through their bisections is a true level, and indicates the line in which the plane of the artificial horizon cuts the object photographed.

Measurements made on the plate, therefore, will indicate how much out of 'plumb' any line may be, and also the angular altitudes of any points (above the plane of the artificial horizon) as well as their azimuths. Photographs of this kind might in many cases be substituted with advantage for plane-table work.

The only adjustment which must be made with any degree of accuracy is the levelling of the camera, that is, ensuring the verticality of the photographic plate. If the plate makes an angle α with the vertical, the images of true vertical lines will converge to a point on the plan of the plate distant from the centre by a quantity proportional to cot α, and the image of a line joining the direct and reflected image of a point the azimuth of which is β and altitude γ makes an angle $\tan \alpha \tan \beta \tan \gamma$ with the true vertical. If α is small (a quarter of a degree or less) the error introduced is for most purposes negligible.

It is unnecessary to describe in detail the reduction of the measurements taken from the negatives, but a few notes on the general result may be of interest at the present time when there seems to be a widely spread notion that modern forms of traffic have an injurious effect on adjacent buildings.

Those who are acquainted with the subject do not require to be reminded that such disturbance of the ground as is caused by traffic has no effect on the stability of buildings, but the belief to the contrary is still common, and cracks and subsidences due to very different agencies are often imputed to 'vibration.'

Such experience as I have had leads me to believe that it is rare to find any building, whether old or new, in which lines intended to be vertical are not measurably out of 'plumb.' In what may be called domestic architecture—cottages and small houses—the errors sometimes approach 1°. For large buildings and factory chimneys, which have presumably been built under some sort of supervision, the inclinations to the vertical are much smaller, often only a few minutes of arc. In mining districts (in which I have not yet had any experience) the effects of subsidence would probably give much larger angles.

In the few old churches to which the method has been applied, I have not found more than 10′ or 12′ deviation from the perpendicular in the towers. For the interior columns, however, this is sometimes exceeded.

Referring to a few particular buildings, I could find no error in the verticality of the western towers of Westminster Abbey or in the Clock Tower of the Houses of Parliament.

The top of Salisbury spire is about 13 inches to the south of the position it should occupy, and the columns which carry its weight have been bent inwards by the thrust of the vaulting of the aisles. Their maximum horizontal displacement is only about 4 inches, but the effect as seen from the west end of the nave is conspicuous. There is, so far as I know, no evidence as to whether the bending took place at the time of the completion of the spire, or later. Something of the same kind happened at Wells, and the inverted arches in that cathedral were introduced as a safeguard.

It is not uncommon to find that foundations have sunk locally as the load placed on them increased, and that building on the sunk foundation has been continued in a more or less true vertical direction, thus introducing a 'kink' in what should have been a straight line. The east end of the church in Smith Square, Westminster, is a good example of this. In St. Paul's Cathedral also there is similar evidence of a local sinkage of foundation during construction, but this cannot be seen from any ordinary point of view.

It would be worth while to obtain, for future reference, a regular series of artificial-horizon photographs of the principal existing buildings both at home and abroad, and these would be particularly interesting for earthquake and mining countries and also for towns built on pile foundations.

I expect it would be found that where buildings have remained unchanged for a few years after completion they would remain unchanged for centuries, provided that the conditions of the ground about the foundations were not interfered with as regards drainage and distribution of pressure, and that where subsidence occurs it is in these directions that the cause should be looked for.

Exeter, January 16.

Acidity of the Medium and Root Production in Coleus.

IN order to test the effect which the reaction of the medium has upon root-production by cuttings, experiments have been made during the summers of 1924 and 1925 with Coleus. It is the practice at the Royal Botanic Garden, Edinburgh, to root in cocoa-nut fibre cuttings which require heat. It was found that the fibre gave a reaction of pH 4·5-4·7, and was very strongly buffered, large additions of acid or alkali being necessary to shift the pH appreciably. (The testing was done with the B.D.H. Capillator, the brown colour of the water squeezed from the fibre causing little trouble in the capillary tube.) In view of this marked buffer action, it is not possible to use this natural fibre for experiment, though it is excellent in practice, being of a light texture and holding a good amount of water without becoming sodden. An artificial medium, comparable to the natural fibre in physical state, of which the reaction can be controlled, has yet to be found. Sand, cotton-wool, and glass-wool, with water, and water alone were tried; only the last proved satisfactory. Experiments were accordingly made with tap-water, adjusted to the required pH by the addition of traces of hydrochloric or sulphuric acids or of sodium carbonate, the normal pH of the water being about 7·3. While these results cannot be directly transferred to the case of fibre, owing to the great differences in oxygen supply, they are at least suggestive.

The cuttings were made at random from plants of a form of *Coleus Blumei*. They were placed in large, carefully cleaned gas-jars, with about two inches of water. The water was changed as often as the indicator showed a marked departure from the initial *p*H—at least once in 24 hours. (All the solutions became more acid, owing to respiratory carbon dioxide: this was proved to be the chief source of acidity by the ease with which a current of carbon dioxide-free air restored the initial *p*H. The following indicators were used: thymol blue, phenol red, brom-phenol blue, di-ethyl red, methyl orange, brom-cresol green. At the dilutions used they were not toxic to the plant in seven days.) The cuttings were thus fully turgid, and no time was lost through preliminary flagging. At the end of the experiment (after seven or fourteen days) the roots of each batch were cut off, and roots and cuttings weighed separately after being dried to constant weight at 100° C. The weight of root corresponding to 1 gram of cutting was taken for comparison.

It was found that rooting would only take place between *p*H 4·0 and *p*H 9·2. Below *p*H 4·0 the ends in contact with the water quickly became soft and died. Within these limits *p*H 7·0–7·2 was the most favourable for root production; and *p*H 4·5 was more favourable than *p*H 9·2. The results for one experiment were:

*p*H 4·5 : 1 gm. cutting corresponds to 0·05540 gm. root.
*p*H 7·2 : 1 ,, ,, ,, 0·08138 ,,
*p*H 9·2 : 1 ,, ,, ,, 0·04318 ,,

Even without weighing, the batch at about *p*H 7·0 was easily seen to be ahead: the roots appeared from one to three days earlier and were usually longer than the others.

The condition of the carbohydrate reserves had a marked influence on the rooting. Two lots of the same form of Coleus were used, one growing in full light and the other in a shaded house. The first had brightly coloured leaves and short red internodes, and the reserves were largely starch, with traces of reducing sugars. The second plant had larger and paler leaves, and longer internodes with no red colour, and the chief reserve was reducing sugar. The 'starch' plants produced more roots and produced them more quickly than the 'sugar' plants, regardless of the reaction of the medium. In all cases there was a basipetal concentration of reserves in the cutting after a few days.

The *p*H values of the tissues of the stem were examined by placing thick sections of fresh material (first washed in neutral water) in dilute solutions of di-ethyl red, methyl red, brom-cresol green, brom-cresol purple. They were found to be as follows: pith 5·2, xylem 4·4, cambium 5·8–6·0, phloem parenchyma, 5·8–6·2, cortex 5·2.

In fibre the cut end of the stem shows an intense reaction with Sudan III., indicating that the cut cells are blocked with fatty substances, and a basal meristem forms callus to a depth of three or four cells. In water the cut end stains only slightly or not at all with Sudan III., and callus formation is inhibited, but in spite of this rooting goes on freely.

These results indicate that the free admission of air is one of the most favourable aspects of the fibre, and suggest that (for this plant at least), given equal supplies of oxygen, a reaction of the medium near neutrality would be preferable.

These experiments are being continued on quantitative lines, in the hope of ascertaining more exactly the optimum reaction of the medium for this plant.

Genes and Linkage Groups in Genetics.

IN making a final reply to Prof. Huxley on the subject of linkage and genes, I should like to say that I resent very strongly his accusation that I refuse to keep to the point which he has raised. I may remind Prof. Huxley that he began the discussion by attacking my review in NATURE of Haecker's "Pluripotenz"; that he asked me for my views on the nature of linkage groups and unit-factors; and that when I answered him as briefly and clearly as possible, he replied by giving a lengthy exposition of the well-known 'results' of the Morgan school of Mendelians.

Prof. Huxley knows perfectly well that I could not deal with such an exposition without examining critically the evidence on which the 'ratios' were based, the value of the mathematical formulæ, and above all, the criteria for discriminating unit-factors, and that to accomplish all these things would be altogether impossible within the ambit of a letter to NATURE. All I could do was to indicate my general scepticism as to the value and soundness of Morgan's methods and to attempt to give my reasons for regarding the whole method of 'factorial analysis' as a futile way of attempting to solve the problems of heredity and mutation. Of course, I never denied that segregation of paternal and maternal characters occurs when a 'mutant' is crossed with the type, and in the "glad confident morning" of Mendelism twenty years ago, it appeared as if it would be an easy task to analyse this segregation into 'factors.' The attempts at this analysis, continued during the present somewhat overclouded afternoon of the theory, have led to such absurd and impossible results that they have induced many besides myself to regard the whole analysis as radically unsound in principle.

By a singular coincidence I have just received from Prof. R. Woltereck a copy of a paper which he has written on the gene for the 'eyeless' mutation in Drosophila (Zur neuen Genetik: II. Einiges über die Augenmutanten von Drosophila und besonders über die Mutation "eyeless," *Die Erde*, vol. 3, Heft 9, 1925). In this paper Prof. Woltereck examines all the work that has been done on this so-called gene. He points out what enormous individual variations are classed together under the head of the single 'unit-factor'; he states that to endeavour to account for these variations by introducing additional unit-factors only obscures the question by bringing in further 'unknowns' into the problem; and he concludes by observing that the only satisfactory way of dealing with the problem is a physiological one, which he enunciates in language almost identical with my own. He says that there is a normal grade of developmental energy in every animal which expresses itself in the typical development of every organ (thus the ommatidia of the Drosophila eye increase to a certain number and then stop); that in the eyeless mutants this energy encounters an increased amount of resistance varying in amount from individual to individual, due to the condition of the 'internal environment.' I should have preferred to say that the developmental energy had suffered different degrees of weakening, but that is a minor point.

As Prof. Huxley still seems to be in doubt as to my meaning, let me state again that I regard a linkage group as caused by a definite form of constitutional weakness, or as I should term it germ-weakness, the linked genes being "outward and visible signs" of this weakness. A good example of a definite type of germ-weakness is afforded by amniotic pressure in the developing vertebrate. This, differing from case to case in its intensity, duration and period of onset, can manifest itself in the most varied groups of 'factors' showing different degrees of 'linkage.' Prof. Huxley says that he does not know what I mean by calling a unit-factor a 'change.' A unit-factor can only be defined and has always been defined by *its deviation from the type*: that is what I meant by calling it a change.

Prof. Huxley refers to the attempts of Stresemann to account for specific differences between birds on the basis of supposititious mendelising mutations. Stresemann is not the only Mendelian who has attempted this futile task: no good systematist known to me will have anything to say to it, and if readers of NATURE wish to convince themselves of the utter bankruptcy of all such efforts, I recommend them to read the latest and most elaborate of them by Goldschmidt ("Untersuchungen zur Genetik der geographischen Variation," *Arch. f. mikr. Anat. u. Entw.-Mech.*, vol. 101, 1924), in which he deals with the geographical races of *Lymantria dispar*. After trying in vain to account for his results by assuming (*pace* Prof. Huxley) Mendelian factors, he is driven back to the assumption of maternal and paternal (!) cytoplasmic influences, and even then does not arrive at a satisfactory solution. He thinks it could perhaps be done by assuming 'modifying factors' (Morgan's patent), but deems such a procedure beneath his dignity. Really, when Prof. Huxley says that Mendelian factors are not 'assumed' one doubts if he realises the meaning of words.

The central fact of biology is adaptation: its central problem is the origin of this adaptation, and until Prof. Huxley recognises this he will continue to flounder in a quagmire of imaginary 'factors,' the number of which will require continual augmentation, as Nature exhibits herself more and more unwilling to be comprised within the narrow formulæ of the geneticists Really, the top-heavy structure already evolved in the imagination of these gentlemen reminds us of nothing so much as the Ptolemaic conception of the heavens "with cycle and epicycle scribbled o'er," which preceded the views of Kepler and Galileo. E. W. MACBRIDE.

Imperial College of Science and Technology,
South Kensington, London, S.W.7.

THE purpose of my letter published in NATURE of January 16, p. 86, was to support, by an example, Prof. MacBride's view that mutations that appear together have some common developmental cause. From Prof. Huxley's letter it seems that the term 'linkage-group' is to be used only if this cause be unknown, when the hypothesis that the characters are associated because their factors are in the same chromosome is less easily disproved.

C. TATE REGAN.

The Palæolithic Drawing of a Horse from Sherborne, Dorset.

IN NATURE of February 13, p. 233, Mr. C. J. Bayzand describes how his leg was pulled by certain boys of Sherborne School (for whose conduct, on their behalf, I wish to apologise to him) with respect to the finding of this inscribed bone.

As I probably know most about the circumstances of the find, I may be allowed to state the facts.

In, if I remember rightly, September 1911, among the new boys who visited the school museum for the first time were A. Cortesi and P. C. Grove, who asked where they could obtain fossils like those in the museum. I directed them to a certain quarry where, as it was being worked, they could find ammonites, etc. In this quarry, on a heap of broken stone, which the workmen told me had come from the opening to an adjacent fissure, still visible, where the rock was much broken, Cortesi, in the presence of Grove (who died in the War), picked up, among other things, a bone, which he handed to the latter, asking if it was a fossil. Grove said "No"; but in giving it back he noticed a drawing upon it. So Cortesi took it to his boarding-house, where in the evening it was examined and thought little of; but when Cortesi was about to throw it into the fire he was stopped by Jefferson (then a boy who had been a year in the school), as stated by him in a recent letter to the headmaster, which I am permitted to send for publication. The bone was accordingly brought to me for inspection, and afterwards given to the school museum by Cortesi.

That two new boys should have made such a discovery was, as any public school boy will understand, not looked upon favourably by many of the older boys, and very soon sides had been taken, for and against, and as "fama viret eundo," the latter party soon changed the locality of the find to a town refuse heap, and would-be recruits were shown how Cortesi must have drawn it, though this was not very effective, for he could not draw "for nuts," as boys say, and the Town Council of Sherborne burned their refuse and do not allow inhabitants to keep horse bones on their premises till they are as brittle as this one.

Eighteen months *later* the quarrymen broke into a narrow cave forming the lower part of the same fissure, and it was then evident that the heap on which the bone was found was composed of the debris from the quarrying away, some years before, of the entrance to this cave, which pointing south-west was situated near the summit of a short narrow valley, now dry from the working back of some of the Somerset streams draining the low land between Sherborne and Glastonbury and the Mendips, and in which, lower down, we have discovered remains of the mammoth and woolly rhinoceros.

Cortesi was always very jealous for his find to be attributed to himself alone, so it is improbable that any one else at Sherborne drew it, and he certainly could not himself. As a hoax on a master, a new boy in a public school, with all his troubles before him and without for some years any privacy, would scarcely think of hoaxing masters he knew nothing about, in fact, Cortesi's letter to the headmaster disposes of anything of that kind.

I have done my best to unravel the mystery of its production, if it is a 'fake,' and I have come to the conclusion, which I hope Prof. Sollas will accept, that it was not manufactured at Sherborne School. Like Mr. Bayzand, I always felt its similarity to Sir W. Boyd Dawkins' Creswell Crag specimen must raise doubts; but since I, as in duty bound, submitted it to the inspection of the members of the Geological Society, my doubts have been somewhat allayed and I have placed my trust and confidence in them, seeing that I am not in a position to be able to express an opinion myself May I therefore, in conclusion, ask some member of that learned society to explain how they got over this difficulty of similarity to the Creswell Crag inscribed bone? R. ELLIOT STEEL

Stalbridge, Dorset,
February 18.

Copy of Part of the Letter of Mr. E. A. Ross Jefferson.

17 Kensington Palace Mansions,
De Vere Gardens, W.8,
12.2.26.

DEAR HEADMASTER—Perhaps I may be able to throw some light on the "Palæolithic Bone." Cortesi showed it to me when he was about to throw it in the day-room fire, and I told him not to be such an Ass; as I had been reading about the Palæolithic Period, and saw at once that the bone was a real find.

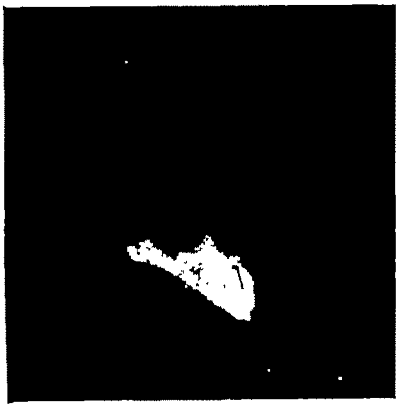
I told him to show it to Bob Steel, which he did; and for that reason it is in the museum to-day.

. . . .

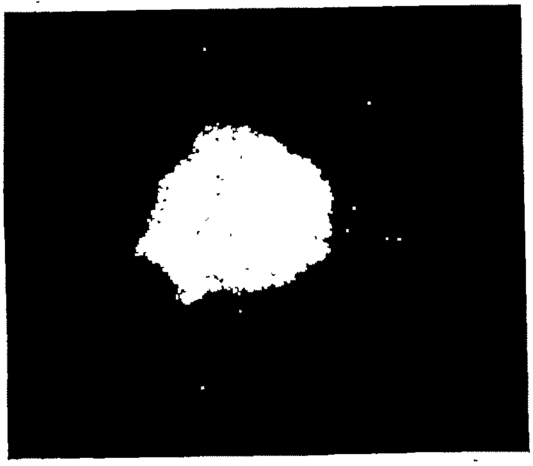
The idea of the bone not being genuine was a rumour started by that arch-humourist, Mr. X.—Yours sincerely, E. A. ROSS JEFFERSON.

A Single Electrode Arc.

THE accompanying photographs (Fig. 1) represent a somewhat extraordinary manifestation—a single electrode arc. The discharge is produced by the application of alternating voltage of the order of 5 kv. at frequencies higher than about 10,000,000 cycles to an electrode consisting of a short length of wire. It may occur spontaneously if the wire is sufficiently thin (0·1 millimetre), with a thicker electrode it must be started by touching the end of the wire with a glass rod, which is then withdrawn. The discharge has the appearance of a flame or arc having one or more tongues up to 15 centimetres long and is coloured faintly by the electrode material.



(a) Copper



(b) Molybdenum

FIG. 1.

If the arc is drawn from the end of the wire it forms a globule of molten metal from which it burns until the temperature of adjacent portions of the wire and/or the diameter of the globule indicate that it should move elsewhere This movement has just taken place in the photograph (Fig 1 (a), copper electrode) in which the molten globule can be seen. In general the movement of the flame is controlled by the melting of the wire. Under the conditions of the experiment the arc consumed about half a kilowatt.

Presumably the production of the arc depends on the frequency being so high that ions of one sign are not wholly collected by the electrode during one half cycle, and that de-ionisation is small during the period when the potential is changing sign.

N. RYLAND DAVIS.
C. R. BURCH.

Research Laboratories,
Metropolitan-Vickers Electrical Company, Ltd.,
Trafford Park, Manchester, January 23.

The Herrings of the Eastern Part of the English Channel.

DURING the great East Anglian herring fishery which takes place during October, November, and part of December, almost all of the fish taken are either spawning or are in the condition which just precedes spawning.

It has been shown that the main areas in which eggs are deposited are near Smith's Knoll L.V., near the Gabbard L.V., and also in the neighbourhood of the Sandettie L.V, and, with the exception of the latter place, that the spawning fish are in the minority. This must mean, then, that there is some other area in which spawning takes place.

In 1923 and 1924 an attempt was made to locate these fish after their disappearance from the Southern Bight in December. Herrings were obtained from Brighton in the winter of 1923–4, and from Swanage in 1924–5, but, on examination, it was shown that they were of a very different type from those of the southern North Sea. These fish, according to the maturity observations, belonged to a shoal which spawned in December-January, but the nature of their annual growth as shown by their scales proved without doubt that they were not fish which had migrated from the North Sea.

In the paper recently published by the Ministry of Agriculture and Fisheries, I have pointed out that there are two groups of herrings in the southern North Sea, and these are classified according to their first year's growth as calculated from the first winter ring on their scales. One group was found to be approximately 8 cm. at the end of its first year, and the second 10 cm. This difference is probably due mainly to the difference in the time of year in which they were spawned.

The fish from the English coast of the Channel were found to be approximately 12 cm. at the end of their first year, and, age for age, were larger than those of the North Sea. The fact that these fish were found in two successive years along the southern English coast made it appear at first very doubtful that the remainder of the East Anglian herrings migrated into the Channel to complete the spawning. It was known that there was a fishery along the French coast during December and January, and also that after this period it was possible with suitable gear to obtain larval herrings in the neighbourhood of Cap d'Antifer; so with this information an investigation was carried out at Boulogne in January this year, with the view of establishing the identity of these herrings.

Below I give an outline of the results obtained.

Fish which were actually spawning, and also some which were newly spent, were obtained, and an examination of their scales was made. Here is the age composition of one of the samples of spawning fish :

Age (years) . .	3	4	5	6	7	8	9	10	
No.	20	64	17	32	8	—	—	3.	Total 144

There are, it will be seen, two main groups, the four-year-olds and the six-year-olds. From the scales of the '4' group I have calculated the length of the fish to the end of each year of their life, and the averages of l_1, l_2, l_3 are found to be 8·55, 16·42, and 20·88 cm. respectively, which, according to the work already published, classes them as southern North Sea herrings.

The peak at '6' is of different composition. Here, without calculation, it is possible to detect two different kinds of growth in the scales—the large Channel type of l_1, and the smaller southern North Sea type—so it is safe to say that while North Sea fish are found spawning along the French coast in winter, there are also Channel fish in the shoal which are spawning at the same time.

W. C. HODGSON.

Fisheries Laboratory,
Lowestoft,
February 2.

Domestic Heating.

I FULLY agree with Mr. Gheury de Bray in the letter on this subject in NATURE of February 6: open fires in a house are immeasurably preferable to electric or gas fires.

For some time past I have studied not only the microscopic structure of coal, but also its vital effects, and I am absolutely convinced, and desire clearly to enunciate, that it is sociologically most important as well as scientifically interesting that the valuable vital effects of a glowing coal fire should be realised. A glowing coal fire gives out something subtle, yet intensely 'nourishing' to the system, 'nourishing' in a way that vitamins and ultra-violet rays are 'nourishing.' Whatever this stimulating influence may be, it is either absent or very weak in radiation from anthracite stoves or gas and electric fires. Hence, for health, a brightly glowing coal fire should be present in every nursery, and in the chief living-room in every house.

Further than this, the curative powers of such a fire are great. An illustration may emphasise this. After a very severe illness, when I had been at death's door, and still suffered with a high temperature and intense weakness, I insisted, to the horrified amazement of the hospital nursing sisters in charge of me, on being lifted from my bed and, protected by screens from draughts, lying naked before a specially prepared brightly glowing coal fire for half an hour. So rapid were the beneficial effects, that in fifteen or twenty minutes even the nurse in charge recognised them as indicated by the steadying and rate of the pulse, the temperature, and a marked improvement in the feel and appearance of the skin, to say nothing of the sense of returning health and increased vitality to which the patient alone could testify. The regular use of the coal fire in this way greatly contributed to my rapid recovery and returned vitality. When overtired or threatened with a cold in the head, whenever possible, I use the same measure, always with beneficial results. This is not due simply to the airing of the skin (most valuable also in its way), as the effect does not result from stripping in a room equally warmed by plated hot pipes and electricity.

At present, when so many homes are being built regardless of the value of the coal fire, or with improperly constructed coal fires, it is important that the plain common-sense man and woman should not allow their common sense to be crushed out of them by pseudo-science which professes that the substitutes offered by gas or electricity are equally effective. The question of fires seems to me at present to be parallel to that of the 'scientific' provision of substitutes like margarine for butter some years ago, when farm women and servants were laughed at by scientists for preferring real butter to margarine, and have since been proved by profounder scientists to be quite right, butter containing vitamins absent in margarine.

What the 'nourishing' substance in a brightly glowing coal fire is, I do not yet know, but it will be found out some day. There are many extraordinarily interesting and subtle points about the composition of coal which are not yet fully investigated. For example, the vitrain bands in an ordinary banded bituminous house coal affect a photographic plate in the dark so as to imprint themselves as a clear image upon it (see Stopes, *Phil. Trans. Roy. Soc.*, 1919, p. 470).

Our race is being weakened by innumerable interferences with our natural physiological processes, and therefore, in the interests of the race, of the health and happiness of the individual, as well as in the name of science, may I emphasise the immense importance of not flouting the natural instinct of the British people to use bright *coal fires*.

MARIE C. STOPES.

Givons Grove,
Leatherhead, Surrey,
February 15.

Conservation of Momentum and the Doppler Principle.

SINCE on the relativity theory mass and energy are related by the equation $Mc^2 = W$, the different energy states of an atom may be thought of as being different mass states of the atom. For example, on the quantum theory when an atom changes from an energy state W_p to an energy state W_q, a quantum $h\nu$ is radiated such that $h\nu = W_p - W_q$ (W_p being supposed greater than W_q), and hence $h\nu$ may be supposed to be produced by a loss of mass in the atom as a whole. We shall therefore consider an atom to have a mass M_p before the emission of a quantum $h\nu$ and a mass M_q after the emission. Each of these masses consists of the rest masses of the various parts of the atom together with the mass due to the kinetic and potential energies of the various parts. Further, although parts of the atom may be moving relatively to each other, we shall suppose that M_p and M_q are the rest masses of the atom as a whole in the two states.

Let us now consider the case where an atom of rest mass M_p is travelling in the direction θ with respect to the OX axis with velocity $\beta_p c$. At a certain instant of time the mass M_p changes to mass M_q and a quantum $h\nu$ is emitted in the OX direction, the atom of rest mass M_q then moving with a velocity $\beta_q c$ in the direction ϕ. The principle of conservation of energy requires

$$\frac{M_p c^2}{\sqrt{1 - \beta_p^2}} = h\nu + \frac{M_q c^2}{\sqrt{1 - \beta_q^2}}, \quad . \quad . \quad (1)$$

while the principle of conservation of momentum requires

$$\frac{M_1\beta_1 c\cos\theta}{\sqrt{1-\beta_1^2}}=\frac{h\nu}{c}+\frac{M_2\beta_2 c\cos\phi}{\sqrt{1-\beta_2^2}}, \quad . \quad . \quad (2)$$

and

$$\frac{M_1\beta_1 c\sin\theta}{\sqrt{1-\beta_1^2}}=\frac{M_2\beta_2 c\sin\phi}{\sqrt{1-\beta_2^2}}. \quad . \quad . \quad (3)$$

Solving for $h\nu$ we find

$$h\nu=\frac{(M_1^2-M_2^2)c^2}{2M_1}\cdot\frac{\sqrt{1-\beta_1^2}}{1-\beta_1\cos\theta}. \quad . \quad . \quad (4)$$

Now, if $\beta_1 c$, the velocity of the atom before the emission of the quantum, is zero, then the quantum emitted is $h\nu_0$, where

$$h\nu_0=(M_1^2-M_2^2)c^2/2M_1, \quad . \quad . \quad (5)$$

so that equation (4) may be written

$$\nu=\nu_0\sqrt{1-\beta_1^2}/(1-\beta_1\cos\theta). \quad . \quad . \quad (6)$$

If β_1 is small, then writing $\beta_1=v/c$ we have

$$\nu=\nu_0\times c/(c-v\cos\theta), \quad . \quad . \quad (7)$$

the formula for the Doppler principle. It seems therefore that the Doppler principle may be deduced without recourse to a wave theory.

If $\beta_1=0$, we may solve for the velocity of recoil $\beta_2 c$ and find

$$\beta_2 c=c(M_1^2-M_2^2)/(M_1^2+M_2^2)$$
$$=2M_1h\nu_0/(M_1^2+M_2^2)c. \quad (8)$$

For light of about 4000 Å.U. emitted by the hydrogen atom:

$\beta_2 c=100$ cm./sec., while $(M_1-M_2)=5\times10^{-33}$ gm.

An Australian Fossil Jelly-fish.

QUITE recently a remarkable discovery of a fossil jelly-fish has been made in the fine-grained blue mudstone of the lower part of the Silurian at Brunswick, Victoria. It was in the same locality, but at a higher horizon, that another unique discovery was made about twenty-four years ago, of an exquisitely preserved crinoid, *Helicocrinus plumosus*, of which the entire organism was found, including the coiled distal end of the column.

The present fossil occurrence is unique for Australia, so far as I am aware, and the only other related form is a Discophyllum (*D. peltatum*) figured and described by James Hall in 1847, from the Hudson River Series, below Troy, New York.

It is especially noteworthy that our basal Melbournian stage of the Silurian comes, in point of geological time, immediately after the American sediments, so that these two widely separated occurrences practically agree both in morphological affinity and in age.

The Victorian Silurian jelly-fish is shown in strong relief on the two halves of a slab. The umbrella is radiately ribbed and concentrically frilled. The genital pockets are distinct and there is a zone of comparatively short tentacles more or less clearly marked.

Notwithstanding the paucity of definitely preserved skeletons of invertebrates, such as mollusca and arthropods, in the Victorian mudstone, very much original structure has been retained in fossils that would not, in the ordinary way, be regarded as good museum specimens. From similar fine-grained mudstones in Victoria, the soft gill-plumes of the Serpula-like Trachyderma have already been described, in which even the eyes are still visible as carbonised spots. There is little doubt that a careful and prolonged search amongst these supposed unfossiliferous mudstones would result in many thrilling discoveries, and it is fortunate that the above fossil fell into the hands of so careful a collector as its discoverer, Mr. R. Evans.

Measurement of Radiation Intensities by Photographic Methods.

DR. HOUSTOUN, referring in NATURE of January 30, p. 159, to Dr. Toy's note on the above, deprecates the use of 'neutral' absorbing screens, and recommends that the intensity of a beam of radiation be reduced by increasing the distance between source and screen and applying the inverse-square law. In view of the simplicity of action and ease of calibration of neutral screens or wedges, it is surprising that at this stage in the development of photometry, a method possessing so many disadvantages as that suggested by Dr. Houstoun should be seriously considered. If large variations in the intensity of radiation are required, say of the order of 2000 to 1, any instrument depending on the direct application of the inverse-square law must necessarily be extremely cumbrous. Further, the effect of reflected radiation from adjacent surfaces is difficult to eliminate, and the necessary correction for the absorption of the intervening medium detracts from the apparent simplicity of the method.

The 'neutral' wedge, on the other hand, provides an accurate and compact means of altering the radiation intensity throughout a very wide range. Wedges can be obtained which are practically neutral over a large portion of the visible spectrum. Even if the absorption varies with wave-length, as it does, for example, in the ultra-violet, the wedge is easily calibrated in its actual position in the apparatus, so that its lack of neutrality is not really detrimental to its use. Again, the wedge produces a continuous change of intensity, whereas any method depending upon the inverse-square law can in practice only change the intensity by finite amounts. Optical wedges have been used here in many different types of researches and have proved both convenient and accurate.

What is a Beam of Light?

PROF. GILBERT LEWIS'S views (NATURE, February 13, p. 236) stretch far, but will he, or any one else, begin at the first stage?

As any group of incandescent atoms must be at every variety of phase of distance, why does any beam of light behave as if it all started from an identic single phase? How can interference appear if two streams of waves moving at every phase interact? There cannot be lamination of space at a wave-length apart, as wave-lengths are varied, and incandescence is the same in all directions.

Another difficulty; in a bundle of waves vibrating in all azimuths, how does polarisation separate the whole light into two parts vibrating at right angles? A selective action might only transmit waves nearly in the same plane, but polarising appears to take all light up to 45° from its plane. Is every separate vibration, or quantum, or corpuscle split into two components?

To the outer layman it looks as if the clearing of these fundamental questions would be a useful preliminary to further theories.

The Species Problem and Evolution.

By O. W. RICHARDS and G. C. ROBSON.

I.

THE object of these articles is to describe and discuss some of the chief attributes of closely allied species in so far as they may cast some light on the process of evolution. The method by which the latter has been brought about is still a matter for discussion, and one of the chief lines of inquiry to which great importance is attached to-day is the intensive study of the early stages of specific divergence. Darwin and the biologists of last century did not, of course, neglect this question; but within the last twenty-five years much has been discovered concerning animal ecology, genetics, and the intensive study of distribution, so that a review of the evolutionary position from these points of view may be of service. The problem will be here discussed principally from the zoological point of view; but some attempt will be made to indicate to what extent the method of evolution in plants is likely to differ from that in animals.

In the course of this discussion it will be seen that no absolute criterion of species can be given. Such distinctions have been sought in structural differences or in some special type of sterility. With regard to the latter criterion, sterility between many forms is well known, but it is uncertain whether there is a special type which can be called specific. Structural discontinuity has been supposed to be a good criterion of species; but the number of characters in which such discontinuity may occur and the degree of discontinuity itself are variable.

In any genus, when the taxonomically described species are compared one with another, it is found that the latter differ in a variable number of structural characters and that no fixed amount can be proposed by which they must differ in order to be called species rather than varieties. Structural discontinuity between such species is sometimes very evident within the limits of a single area; but it frequently becomes much less marked when a complete range of such forms is investigated. In the majority of cases specific distinction is based on the examination of a few characters only which are selected for convenience, and, as a result, the actual amount of difference between species is often doubtful in a particular case. However, in spite of the lack of an absolute criterion, the majority of forms recognised as species by taxonomists represent within broad limits a certain grade of divergence in structure and habit, and are frequently sterile, when crossed.

Some palæontologists have shown that certain forms occurring in successive strata are continuously connected by 'intermediates,' and have thought that the species concept, as it is employed by zoologists, is inapplicable to series of forms in which only the lineage of single characters can be traced. In the first case our knowledge of the relationship of different specimens must be confused by the effects of the environmental conditions which they have experienced; while the second phenomenon has not been shown to be widely spread, and in many groups species may remain well defined over long periods of time.

SPECIFIC CHARACTERS.

Specific differentiation may show itself in several ways, namely, in (1) structure, (2) physiological activities, (3) reproduction, (4) habitat-preference, (5) food, (6) special types of behaviour. When species differ in habits or structure it is probable that they differ physiologically as well, though it is difficult to show a correlation between such differences and any particular physiological process. The result is, therefore, that in practice species are distinguished by differences in their habits and structure because it is not yet possible to do so by reference to their more fundamental properties. The term physiological difference is here used in the narrow sense of difference in metabolism.

1. STRUCTURE. — Constant structural differences between species occur in all organisms from the simplest to the most complex with the exception of the Bacteria, in which, according to the present view, the physiological differences are those which can be best employed for the recognition of species. In the Spirochaeta structural and physiological characters seem to be of equal importance. A comparison between the species or races of Bacteria and those of higher organisms is of doubtful value because of the more rapid multiplication of the former. In the higher plants, structural characters may show a remarkable amount of plasticity; among animals, some, such as the corals and particular genera of other groups, are equally plastic. Not enough is yet known to enable us to say whether the degree of plasticity is a real difference between animals and plants. If such a difference exists it is more likely to occur between motile and sessile organisms.

When closely allied species in various phyla are examined, it seems to result on the whole that no particular organ or system is especially differentiated. The differences that occur usually consist of slight divergencies in size, proportion, and colour and in the number of individual parts, such as the cusps of teeth or 'ornamental' bosses and lines on shells. On the other hand, in certain groups there is no doubt that secondary sexual characters stand out as being affected; though in some these are scarcely differentiated at all, for example in the Polychaeta, the Lamellibranchia, and some Prosobranchiate gastropods.

Of those forms which show such differences, some exhibit them in the organs connected with copulation, for example many of the Platyhelmia, a large proportion of the Arthropoda, Pulmonate gastropods, and many groups of mammals; while in birds other secondary sexual characters are affected. No other generalisation as to the structural characters which distinguish closely allied forms can be made; but the following points are worthy of attention. Species often differ in the frequency with which certain characters occur together; thus the common limpet (*Patella vulgata*) differs from the "flither" or low-water limpet (*Patella athletica*), with which it has many features in common, in that it possesses more frequently a broad shell and a grey foot, while the flither usually has a narrow shell and an orange-yellow foot. Many allied forms differ in total body size, though if their sizes were plotted graphically the frequency curves would overlap considerably.

It has been pointed out frequently that allied species tend to throw parallel variations; but it is equally true that one of two closely allied forms may be distinguished by its ability to throw some particular variant, for example, the fly *Dorniphora abdominalis* always has two antero-dorsal bristles on the hind tibia, while *D. florea* may have two or three (Lundbeck, 1922). Furthermore, species may be polymorphic in one part of their range and not in another, so that their races may differ in the ability to produce certain variants.

Colour differences between species are often held to be of great importance, but many cases are known in which such differences do not obtain, and it is uncertain whether colour is markedly affected at the onset of divergence. Some colour differences, for example melanism, constitute special problems which cannot readily be explained.

2. Physiological Differences.—Differences between species of the same genus have been reported in many activities and properties which we define as physiological and biochemical; for example, in actual metabolic processes and their products (including special secretions such as venoms), in the fertilisation reaction, and in the behaviour of grafts. In a wide sense physiological distinction is ultimately implied in all differences of structure and habit. If we consider measurable differences in metabolism only, it is very difficult to say whether a physiological differentiation parallel to that of structure is at all universal. The study of such processes is usually limited to different genera, and the differences between species are not often considered. Furthermore, when species of the same genus are examined, no allowance is made for individual idiosyncrasy, sexual and seasonal difference, and other factors important from the taxonomic point of view. There remains, however, some evidence which suggests that taxonomic species may be as clearly differentiated in their metabolic activities and products as in their structure; for example, in carbon dioxide output, certain properties of hæmoglobin, amount of blood-sugar, starches of plants, and the precipitin reaction of vertebrate blood. The data on most of these points, however, require investigation from the taxonomic point of view, and there is furthermore a real need for the study of the physiological differentia of closely allied species.

3. Reproduction.—The phenomena to be considered here include (*a*) breeding season, (*b*) mating habits, (*c*) coitus, (*d*) sterility, and may be considered in two ways, first as criteria of species and secondly as means of isolation. The latter will be more fully considered in a later section.

(*a*) *Breeding Season.*—In those parts of the world where there is marked seasonal change in physical conditions, the breeding period of animals and plants is more or less determined by such change, but within the somewhat wide limits of the general breeding period allied species may breed at different times. These differences may be absolute so that such forms cannot interbreed, or the two breeding seasons may have a larger or smaller amount of overlap. Some species, however, breed throughout the year even in temperate regions, while some allied forms breed at the same time of the year. We do not think there is at present enough evidence to determine whether differences in the breeding season are frequent in closely allied species.

(*b*) *Mating Habits.*—There are two main divisions of this subject—differences in mating-place and differences in mating-behaviour. Neither of these exist in many animals (*e.g.* sessile forms), and in others there is no definite mating-place as distinct from the general habitat.

Mating-Place.—In many cases physical conditions, such as light and temperature, control mating to a considerable extent, and it is quite possible that allied species may be isolated by definite requirements. Very little exact evidence, however, is available on this point. Many species choose particular mating-places which may or may not coincide with the nesting site. Thus Kemp (1915) records that while in *Palæmon malcolmsi* the male probably fertilises the female in fresh water outside the Chilka lake, in *P. rudis* the male accompanies the female into the lake. Both these species perform their migration when the lake is full of fresh water, while a third species, *P. lamarrei*, migrates into it in the brackish season. Comparable cases occur in fishes and birds. When the choice of mating-place involves migration the latter may take place from one particular area to another, so that allied forms are separated throughout the year; or it may take place from an area in which many species live together to a special area. In particular cases this choice of breeding-area may lead to isolation; though how often this results is uncertain.

Mating-Behaviour.—The complex behaviour that often occurs in this connexion may be divided into (1) expressions of excitement, (2) incitement and suggestion, and (3) various types of preliminary manipulation of the female. The second may include either specially developed ceremonies, for example the display by spiders of a special coloured patch, or the abortive use of behaviour included in (3); for example, in many insects the male will jump on the female's back long before coitus. Instances of specific differentiation may be found in all these types, but it is possible that it may be more marked in the second. When differences occur they are often as diagnostic as structural characters.

(*c*) *Copulation.*—The mechanics of coitus involve a complicated adjustment of the musculature and skeletal parts. Differentiation of the latter may be very frequent in intromittent and receptor organs and in parts developed for clasping. Connected perhaps with structural differences are differences in posture and the duration of coitus.

(*d*) *Sterility.*—The sterility which occurs when two species are crossed has often been supposed to be a special characteristic of such crosses. The incidence of sterility is, however, capricious, and no absolute correlation between it and structural divergence can be shown. There is, therefore, a danger of arguing in a circle as to the relationship of species, according as one or the other criterion is used. At present it is only the structural criterion which can be employed satisfactorily; for by this method the degree of sterility and other phenomena difficult of interpretation can be referred to a standard more easily fixed.

The capricious incidence of sterility was known to such an early worker as Kölreuter, and was further emphasised by Darwin and later workers. While sterility is well substantiated among species-crosses in general, the evidence is at present insufficient to decide whether *closely allied* forms are usually sterile. Various forms (for example, species of Drosophila and Poecilopsis), which must be regarded as very closely allied, show a high degree of sterility when crossed. On the other hand, fertility of varying degree may occur between structurally distinct forms which have even been placed in different genera, *e.g.* the mallard and pintail (Philipps 1915); *Xiphophorus strigatus* and *Platypoecilius maculatus* (Gerscheler 1914). In the Teleost crosses made by Newman (1916) one effected between different orders was as successful as that between species of the same genus. Thus it is evident that sterility does not necessarily precede structural divergence and is probably produced in many cases as the sequel to a certain degree of general differentiation. This view is substantiated by the occurrence of many degrees of sterility, of which the following are some examples :—

1. Absolute sterility. (*Poecilopsis isabellæ* and *lapponaria*, Harrison)
2. F^1 produced but with disturbed sex ratio, low vitality, or other abnormality. (Lymantria, Goldschmidt; certain Bistoninæ, Harrison.)
3. F^1 normal but sterile. (Mule.)
4. F^1 produced but weak. (*Drepana curvatula* and *falcataria*, Standfuss.)
5. F^1 healthy. (Antirrhinum, Baur; Bistoninæ, Harrison.)

Between most of the categories no definite distinction can be drawn; as, for example, two forms can only logically be called absolutely sterile if the sperm is unable to enter the egg, yet in practice they will be called sterile if the embryos are produced but die in early stages. If the embryos live a little longer they will be regarded as a sickly F^1. In addition to the categories listed above, it is sometimes found that the result of a cross between species depends on which of them provides the male and which the female.

In discussing sterility there is a danger of identifying phenomena which are only apparently similar (cf. Bateson 1912) and also of confusing sterility produced by unnatural condition with that due to genetic incompatibility. It is sometimes found that crosses at first unsuccessful are, under different conditions, quite fertile.

4. HABITAT-PREFERENCE.—In plants the habitat depends mainly on the physical and chemical factors of the environment, but in many animals an active search for more or less diverse foods determines the exact habitat almost as much as the other factors. Thus two species occurring in one plant habitat, but seeking diverse foods, may be exposed to very different conditions of competition and experience a certain measure of isolation.

Closely allied species of animals and plants may be found in different geographical areas or in habitats differentiated within the same area, and, so far as animals at least are concerned, our knowledge of their distribution is largely founded on the former. The importance of such geographical isolation is, however, uncertain unless at the same time the actual habits and mode of life are known. No two habitats in different countries perhaps can be identical, at any rate in the conditions of competition; yet conditions may be sufficiently similar for the amount of divergence attributable to them to be unimportant.

The occurrence amongst the majority of animals of specific differences in habitat between close allies is not easy to show at present. The geographical range of species may be known, but even in the commonest forms the number of plant-habitats, for example, in which they occur may be very uncertain. Amongst the forms of which the distribution is satisfactorily known, some species occur in the same habitat as their close allies, and some occur in separate ones. The common view that allied species always occur in separate habitats is by no means true. In many mammals the separation seems to be fairly complete; but this is not the case in some insects and Mollusca. When a species occurs in a particular habitat, it is often not restricted to it by a general adaptation but by a reaction to a particular factor. A habitat is usually defined by many factors, and the occurrence of a species in a particular habitat may be determined by different factors in different parts of its range. Structural modifications shown to be adapted to particular habitats or modes of life seem to be more characteristic of genera or groups of higher rank than of species. Thus, when allied species do occur in different habitats, it may not be because of any simple difference in them which could be the result of a single variation.

5. DIFFERENCES IN FOOD.—When animals live on organic débris or on food in solution, it is obviously impossible to say whether there is any difference of diet between species. When the feeding habits are more specialised, the food eaten by any species may consist of the members of a single species or genus, or of a larger range of forms. Differences in diet are not easily detected unless the range of foods is small; for when the diet is more varied a difference between allied species may relate only to a few components of the diet. In the latter case, the food-habits are rarely known well enough to differentiate species. Among insects there are many closely allied vegetarian forms which can be distinguished by the food-plant, though it is probable that such cases are not frequent in the rest of the animal kingdom. With a few exceptions, there is very little satisfactory evidence as to differences between closely allied species in this respect. When parasites are limited to specific hosts their distribution is probably determined by many factors besides food.

6. MISCELLANEOUS DIFFERENCES.—Many differences in habit between species will be recalled which are not considered in the previous discussion. The following are a few well-authenticated examples in closely allied forms. In the moths of the genus Nepticula, the larvæ of which are leaf-miners, the species are sometimes distinguished by the shape of the mine and sometimes by the way in which the larvæ dispose of their dung (Tutt 1899). G. T. Lyle (1925) records differences in closely allied species of Apanteles in the method of making cocoons. Closely allied forms of birds may differ in the degree of their timidity towards man (for example, the British and Continental robins) and in their alarm notes (meadow and tree pipits). Such cases show that habits just as structure are liable to differ specifically.

(*To be continued.*)

Stresses in Buildings.

By Prof. E. G. Coker, F.R.S.

The range and variety of the problems connected with the provision of safe and suitable buildings and structures have recently been brought to the attention of the British public in many ways, notably by a lack of housing accommodation, the insecurity of Waterloo Bridge, and the dangerous state of St. Paul's Cathedral. During the post-War period, the provision of new materials and improved methods of construction have also engaged the attention of eminent architects, engineers, and firms of constructors. Commercial buildings are in the main proceeding apace, where great capital interests are involved, as in Regent Street, London, or where private munificence is supplying the urgent needs of hospitals and educational institutions. New technical problems are in consequence arising, and will no doubt continue to present themselves under a condition of affairs in which methods of construction are rapidly changing and new materials are being pressed into service.

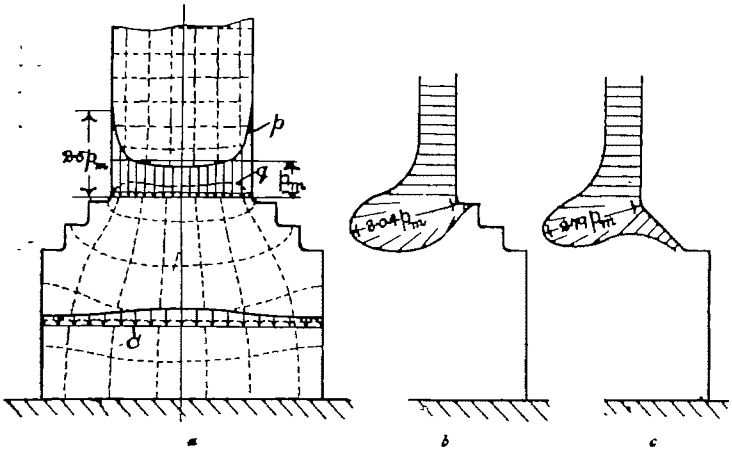

Fig. 1.—Stress distribution and lines of principal stress at the base of a wall.

Some elementary problems of this kind presented themselves recently during the partial completion of the engineering wing of University College, London, upon foundations built thirty years ago. These difficulties were dealt with successfully as they arose, but the absence of definite data in existing literature led to an experimental investigation on transparent models,[1] in which stress is measured by the temporary double refraction produced by load. One of these primary problems is the stress at the junction of a main wall with an enlarged base spread out in the usual fashion shown by Fig. 1, *a*, to afford a safe load on the earth below it.

It is at once apparent that, at the first sudden enlargement in such a wall, the stress at the angles must be extremely great, as experiments show, but for experimental purposes it is necessary to avoid an excessive concentration of stress at such places in order to measure the distribution. All such angles were, therefore, completed by a small circular arc in this case of radius $b/24$, where b is the breadth of the wall. With this modified arrangement, it was found that the stress at the horizontal cross section due to a mean vertical stress p_m rose to approximately $2{\cdot}5\ p_m$ at the junction with the wall, but is even greater at a point on the circular fillet just below this where it rose to $3{\cdot}04\ p_m$ (Fig. 1, *b*). The general vertical distribution p over this cross section is also accompanied by a variable cross stress q as indicated, while at *C*, well below the change of section, the tendency of the stress is to concentrate towards the centre, as my colleague, Prof. Filon, had already shown, mathematically, must be the case. It will also be noted from Fig. 1, *a*, that in the wall the tendency is exactly opposite. Monolithic walls are not usually constructed with stepped footings, but are connected to the base by sloping sides such as may be obtained when the projecting angles, Fig. 1, *a*, are removed, as in Fig. 1, *c*. This is found to result in a diminution of the maximum stress at the face of the wall to $2{\cdot}79\ p_m$.

Another problem of frequent occurrence is the stress effect due to a line of window openings, and represented here by two rectangular openings with rounded angles, Fig. 2, in a wall of limited width, such as might occur with some modifications and many more windows in a monolithic concrete wall of a building. The stress distribution here shows that at the cross section *AB*, the central part of the wall is under practically uniform stress, while the side walls are under nearly uniformly varying stress with maximum values at the window openings, accompanied by great local concentrations of stress at the rounded angles, and variable tension along the upper and lower boundaries of the window openings. This latter stress is unsuitable for masonry, brickwork, or concrete to bear, unless reinforced by steel, or, as in a high building, dealt with by a steel framework, which transmits the main load to the

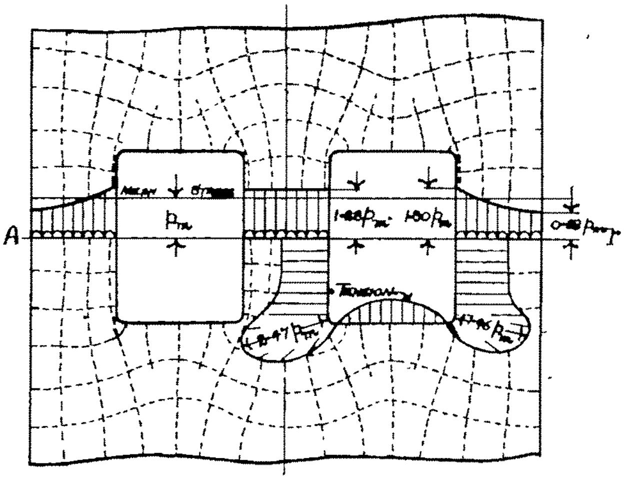

Fig. 2.—Stress distribution and lines of principal stress due to window openings.

---

[1] For a description of the experiments, see the issue of February 6 of the *Journal of the Royal Institute of British Architects*.

foundations, leaving the walls a mere protecting cover of no structural importance.

Structural weakness in a building may also be produced by an excess of material placed there from purely artistic considerations, and a good example of this is an ornamental cornice, Fig. 3, such as may be found in, say, a Gothic cathedral structure. The effect of the projecting part is to cause a considerable change in the vertical directions of the lines of stress, as Fig. 3 indicates. Such lines are also found in the free projecting part and direct attention to the stress there. An examination of the stress across the horizontal joints shows that there is a great local increase of load at the face of the wall, which in this case causes an increase of stress of about 75 per cent. of the mean stress at this face, and is also approximately the same at the outermost point of the lower joint. It may happen, therefore, due to sinking of the foundations at one place, that a good deal of extra load may be thrown on another part of a wall, and the extra stress on a cornice may then rise to so great a value that the material at the face is crushed locally and cracks develop, which ultimately lead to the cornice falling down, as occasionally happens. The reason for this concentration of stress is not difficult to understand, if it is remembered that, in a simple rectangular block of masonry with plane joints and without projections, the compression stress is uniformly distributed, and the two horizontal faces approach one another by a small definite amount.

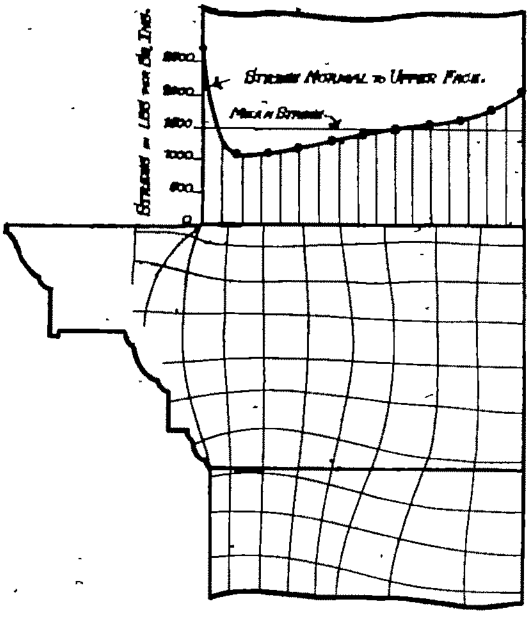

FIG. 3.—Stress effect of a cornice.

The effect of a projection such as a cornice is to resist alterations of the form of the block, more especially in its own neighbourhood, and in consequence the plane surfaces of the joints deform into slightly curved surfaces resulting in a higher stress developing at the ends and more especially at the face of the wall.

This example is one of many instances in construction where an addition of material causes increased stress, which must be taken into account where architectural or other requirements compel the use of excess of material in disadvantageous positions. Experiment in this case shows that some slight improvement in stress conditions is obtained when the cornice is itself of much less depth than the masonry block.

Obituary.

PROF. A. PEROT.

THE death of Prof. Alfred Perot on November 28, 1925, was a serious loss to French science. Perot was born at Nancy in 1863, and after completing his studies at the École Polytechnique at Paris, returned in 1884 to the University of his native town, where he undertook research upon the density of saturated vapours, obtaining experimental confirmation of the thermodynamic formulæ. In 1884 he commenced teaching at the University of Marseilles, where he also undertook investigations on the properties of dielectrics, and on Hertzian waves, and ultimately became associated with Charles Fabry in a series of researches on optical interference, particularly between plane parallel semi-silvered surfaces. The methods developed by Perot and Fabry have formed the basis for the precise determination of the values of the reference lines in the international system of wave-lengths now universally employed.

In 1901 Perot was entrusted with the task of organising a "Laboratoire d'Essais" in connexion with the Conservatoire des Arts et Métiers. While engaged on this task he continued his association with Fabry, and with the further collaboration of the late Dr. R. Benoit, then director of the Bureau International des Poids et Mesures, carried out by new methods a fundamental determination of the value of the metre in terms of the wave-length of the cadium red line, the result of which confirmed with truly remarkable precision the earlier determination of Michelson and Benoit. This determination remains the recognised standard of departure for wave-length values to the present time.

In 1908 Perot left the Laboratoire d'Essais to become professor at the École Polytechnique, and physical astronomer of the Observatory of Meudon, resuming his spectroscopic studies, particularly with respect to very small displacements of lines in the solar spectrum due to various causes. He continued to occupy himself with questions of measures and units, and succeeded M. B. Violle as president of the Commission de Métrologie Usuelle, in connexion with the French weights and measures service. He also took an active part, as president of the Special Commission de Refonte des Règles, in the preparation of the new French law on the subject (1923) whereby the definitions of the metric system were extended and amplified (for example, by the introduction of a system of units based on the metre, tonne and second [M] [T] [S]), with the view of increasing their applicability to the ordinary transactions of commerce and industry.

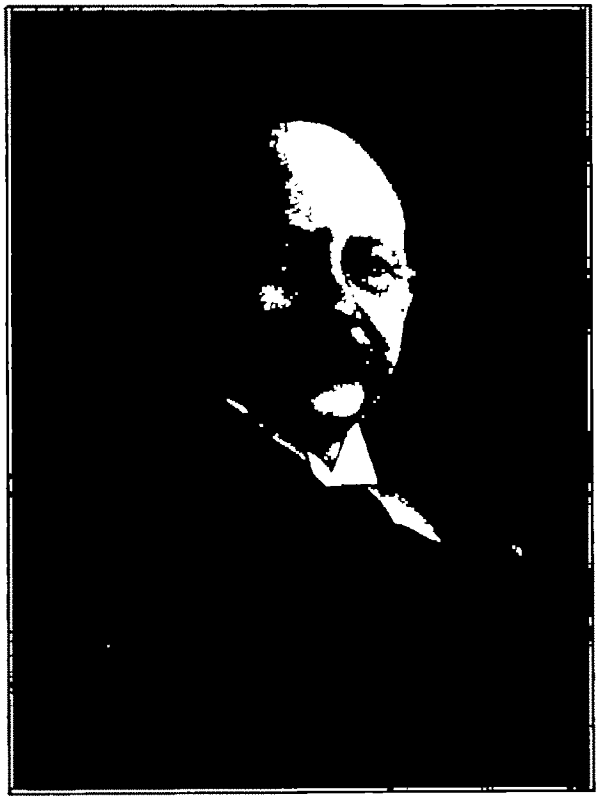
Perot was not only a sound theoretician and skilled experimenter, but also an excellent mechanic, who was well able to construct with his own hands the very delicate apparatus used in some of his investigations. During the War his time was mainly devoted to confidential researches connected therewith.

J. E. S.

PROF. H. KAMERLINGH ONNES, FOR. MEM. R.S.

PROF. HEIKE KAMERLINGH ONNES, whose death on February 21 will be widely regretted, was born on September 21, 1853, in Groningen. As a youth he attended a school in that town, of which J. M. Van Bemmelen, who later became professor at Leyden, and whose name will always be remembered in connexion with colloid chemistry, was principal.

In 1870 Onnes became a student at the University of Groningen, and from 1871 until 1873 he worked under Bunsen and Kirchhoff at Heidelberg. He remained in Groningen until 1878. His doctoral dissertation was entitled "New Considerations on the Axial Changes of the Earth," and was marked by the combination of theory and accurate experiment which is characteristic of all his later works. In 1881 he became influenced by the theories of Van der Waals and wrote an important paper in which he deduced the law of corresponding states from considerations of statistical mechanics.



HEIKE KAMERLINGH ONNES.

In the following year Onnes became professor at Leyden. In his inaugural address he insisted that the laws of physics could be determined by accurate experiment alone. His motto "From measurement to knowledge" was then stated for the first time, and his remarks upon the necessity of the then recently designed pumps of Cailletet and Pictet for the attainment of low temperatures were almost prophetic. It was about this time that Onnes planned his cryogenic programme, which has since made his name famous throughout the world. In 1894 he published his first paper on the design and equipment of the Leyden laboratories, and in his inaugural address in 1894 he laid down the importance of accurate measurements at very low temperatures.

The formation of the cryogenic laboratory at Leyden was only made possible by the extraordinary energy and tenacity, combined with organising talents of a very high degree, which Onnes brought to bear on this subject. As a preliminary it was necessary for him to train mechanics and glass-blowers, and as a result of many years of patient work he obtained an organisation which is still unique. In 1904 Onnes was able to control large supplies of liquid air. By 1906 he had developed the technique of the liquefaction of hydrogen on a large scale. In 1908 he attained the triumph of his career by liquefying helium. This feat, taking into consideration the limited supplies of helium and the difficulty in obtaining it in those days, was little short of superhuman.

The amount of careful organisation and planning necessary before the experiments were started can only be appreciated by those who have seen the laboratory in action. It is worthy of record that the whole staff was so tired out by their exertions that they could not see the helium even after it was liquefied. The presence of the liquid was pointed out to them by Prof. F. A. H. Schreinemakers, who was in the laboratory at the time.

The boiling-point of helium enabled Onnes to reach a temperature only 4·22° above absolute zero. By reducing the pressure he was finally enabled to arrive at a temperature of 0·9° absolute. The writer had the privilege of seeing Onnes attempt to solidify helium. A battery of fifteen large Langmuir pumps were put into connexion with a supply of liquid helium whereby the pressure was reduced to about 0·2 mm.; in spite of this, however, the helium did not solidify.

The ability to control really low temperatures enabled Onnes to make the astonishing discovery of supra-conductivity. It had always been assumed that the conductivity of a metal would run out to nil at the absolute zero. Onnes discovered that quite a number of substances showed a sharp discontinuity in their conductivity curves at a temperature of about 4° or 5° absolute. Typical examples are lead and cadmium. He passed a current of 1000 am./sq.mm. through a conductor under these conditions without being able to detect the slightest change of E.M.F.

Onnes's work is well summarised in the volume presented to him on the occasion of the fortieth anniversary of his holding the chair at the University of Leyden. Most of his work was published in the *Proceedings of the Physical Laboratory of Leyden*, and it is due to the comparative inaccessibility of this publication that Onnes's work is not so widely known as it should be.

It is impossible, within the limits of a brief notice, to give more than an idea of the scope and range of his activities. The division of the above-mentioned work into thermodynamic, magnetic, optical, magneto-optical, radioactive and electric sub-sections, in each of which he published numerous papers, is an indication of the magnitude of his work.

In later life Onnes received the fullest recognition of his great talents. His own country awarded him a Commandership in the Order of the Lion of the Netherlands. Similar decorations were conferred upon him by the Governments of Poland and Norway. In 1913 he received a Nobel Prize for physics. He was an honorary member of practically every learned society in the world. Onnes was awarded the Rumford medal of the Royal Society in 1912 and was elected a foreign member of the Society in 1916.

Turning to his personal side, it is impossible to speak of him without emotion. Onnes was one of the most genial, kind-hearted, and accessible men who ever lived. He made unremitting efforts towards the feeding of children in the destitute areas of Europe in the years immediately following the War. To young men, he was an inspiration. The writer will always remember, with gratitude, his extraordinary kindness and hospitality. He practically kept 'open house.'

Onnes's scientific memory is imperishable, and his personality will never be forgotten by any one who had the privilege of knowing him.

F. A. FREETH.

PROF. F. Y. EDGEWORTH.

BY the death of Prof. Francis Ysidro Edgeworth, fellow of All Souls College and emeritus professor of political economy at Oxford, on February 13, at eighty-one years of age, economists and statisticians alike have suffered a heavy loss. Born at Edgeworthstown, Ireland, in 1845, he was educated at Trinity College, Dublin, and Balliol College, Oxford, and was called to the Bar in 1877. Always a man of the widest interests—classic, mathematician, and philosopher—he was some time in finding his *métier*. Ethics and logic first gave scope to his abilities, but with his appointment as Tooke professor of political economy at King's College, London, in 1890, and his migration to Oxford as Drummond professor in 1891, the trend of his life's work was fixed.

On the foundation of the Royal Economic Society in 1890, Edgeworth became editor of its organ, the *Economic Journal*, and but for one short interval remained co-editor until his death. His early volume, "Mathematical Psychics" (Kegan Paul, 1881), dealing with the application of mathematical methods to economics, is in many ways very characteristic, not only in subject but also in style; in the fact that nearly half the small volume consists of appendices, as many of his later papers bristle with footnotes, and in the adornment of the text by quotations from the Greek. Olympian Zeus, Here, and Athena are but rare visitors to the pages of most economists! His numerous economic writings, for the most part on abstract theory and covering a very wide field, were recently reprinted by the Society in three handsome volumes (Macmillan and Co., 1925), and well exhibit the detached and acutely analytical character of his mind. A fellow of the Royal Statistical Society since 1883, he was awarded the Guy gold medal of the Society in 1907, and in 1912–14 held the office of president.

In statistics, Edgeworth's work was mostly concerned with the theory of error, averages, the normal distribution and its generalisations, and—as mundane a subject as perhaps he cared to touch—index-numbers. He was secretary of the British Association Committee "appointed for the purpose of investigating the best methods of ascertaining and measuring variations in the value of the monetary standard" and responsible for its classical reports (1887–90). The subjects chosen for his two presidential addresses to the Royal Statistical Society, "On the Use of the Theory of Probabilities in Statistics relating to Society" (1912) and "On the Use of Analytical Geometry to represent Certain Kinds of Statistics" (1913), show the bent of his mind. From the first paper he contributed to the very last—a note on "The Element of Probability in Index-numbers" in the *Journal of the Royal Statistical Society* for last July—all exhibit his lively but distinctly difficult style, leaping from one illustration to another: fluctuations of sampling in human statistics elucidated indifferently by counts he had made of the numbers of wasps entering and leaving a nest, or the numbers of dactyls in Virgilian hexameters. Young to the last, in spite of his years, courteous, humorous, and kindly, he will be greatly missed.

REV. S. J. WHITMEE.

THE Rev. Samuel James Whitmee, who died in London on December 10, was born at Stagsden, Bedfordshire, in 1838, and went to Samoa on behalf of the London Missionary Society in 1863, where he remained until 1877. During this period he contributed many notes to NATURE, including "Earthquakes in the Samoan Islands, South Pacific," "Origin of Cyclones," "Meteors in South Pacific," "Fauna and Flora of New Guinea and the Pacific Islands," and in vol. 12 (1875) a criticism of Prof. Dana's review of Darwin's "Coral Reefs," entitled "Mr. Darwin and Prof. Dana on the Influence of Volcanic Action in preventing the Growth of Corals." His other publication included a list of Samoan birds in *Ibis*, vol. 5; "On the Manifestation of Anger, Fear and other Passions in Fishes" in the *Proceedings of the Zoological Society* for 1878; and a paper on "The Ethnology of the Pacific" in the *Victoria Institute Journal*, vol. 14 (1881).

Mr. Whitmee collected and forwarded to Kew numerous botanical specimens, the ferns of which formed the subject of two papers by Dr. J. G. Baker in the *Journal of Botany* for 1876, in which fourteen new species were described. His other natural history specimens were sent to the British Museum.

Returning to England in 1877, Mr. Whitmee engaged in ministerial work, but returned to Samoa in 1891, where he became the close friend of R. L. Stevenson, to whom he taught the Samoan language. Whitmee finally returned to England in 1894 and settled down at Barnet.

C. H. W.

WE regret to announce the following deaths:

Prof. A. R. Cushny, F.R.S., professor of materia medica and pharmacology in the University of Edinburgh, on February 25, aged sixty years.

Prof. F. Roth, emeritus professor of forestry in the University of Michigan, known for his work on the technical properties of timber, on December 4, aged sixty-seven years.

Mr. W. F. Wells, president in 1911 of the British Pharmaceutical Conference and twice president of the Pharmaceutical Society of Ireland, on January 28, aged seventy-six years.

News and Views.

GENERAL satisfaction will be felt at the fact that the Board of Trade has appointed to the Comptrollership of the Patent Office a man who is qualified for the post by definite scientific training. Mr. W. S. Jarratt, the new Comptroller, after becoming an Associate of the Royal College of Science spent some time in research under Sir Norman Lockyer. He next went to Trinity College, Cambridge, as a scholar, became a wrangler, and also obtained a first class in the Natural Sciences Tripos. He then entered the Patent Office as an assistant examiner, and eventually was appointed Assistant Comptroller for Trade Marks. He was called to the Bar in 1910. This is the first time that a Comptroller having scientific qualifications has ever been appointed. Since it became known twelve months ago that ill health was likely to compel the retirement of Mr. Temple Franks, who has done so much by the soundness of his judicial decisions to raise the legal status of the Patent Office to a high level, the problem of the selection of a successor has caused considerable anxiety in circles representing applied science and invention.

THE importance for industry of the principle that the head of the Patent Office should be a scientific man was pointed out some time ago in our columns, and much public interest in the whole question has been aroused. It is believed that the wise step taken by the Board of Trade has given widespread satisfaction, for although strong pleas have been put forward for the policy of raising the salary of the Comptrollership to a substantial figure and throwing the appointment open to general competition, the present demand for public economy must have precluded the adoption of such a plan, and the Treasury may be considered singularly fortunate to have obtained by more conservative measures a man with such excellent qualifications for the post. The position of the new Comptroller is not likely to prove a bed of roses, for there is an urgent demand for various reforms in the patent system, and it will fall to him to advise the Government as to any new legislation which may be necessary in this connexion. It seems safe to assure him, however, of the sympathy and support of the scientific world in handling the intricate and difficult problems which confront him.

FOLLOWING the application of the surgeon's knife to the excessively swollen capital of the British Dyestuffs Corporation, Ltd., the patient is beginning to show signs of convalescence and new energy. On February 26 it was officially announced that the Corporation had acquired a majority of the share capital of Scottish Dyes, Ltd., and that the management of the latter company would continue in the same hands, Mr. James Morton remaining chairman and Dr. J. Thomas, managing director. The board of the Corporation, which was recently strengthened by the appointment of Dr. A. Rée, will now receive the expert assistance of Mr. Morton; and the accession of Sir William Pope to the board of Scottish Dyes, Ltd., will be hailed with satisfaction by the many who believe that no board of this kind is complete unless science is adequately represented upon it. It is also announced that in future the manufacture of vat-dyestuffs will be concentrated at the works of Scottish Dyes, at Grangemouth.

THE process of aggregating brains and capital and of segregating manufacture to chosen works, which seems to be the policy of the British Dyestuffs Corporation, Ltd., is familiar to us from the history of the *Interessengemeinschaft*, and we see no reason why its success in Germany should not find a parallel in Great Britain. During the War, Mr. James Morton showed great enterprise in embarking upon the perilous sea of dyestuff manufacture, and by successfully specialising in the production of 'shades,' he acquired a well-deserved reputation. Since then he has initiated and developed the manufacture of vat dyes at Grangemouth; in fact, his policy has been almost the reverse of that pursued by the Government-aided corporation, which, in its endeavour to monopolise the home industry, entered indiscriminately upon the manufacture of a host of products, with the result that it brought few of them to a state of perfection. At the time when demand greatly outran supply, the latter policy was intelligible, but now that dye-producing capacity is everywhere in excess of consumers' needs, the only way of salvation is to concentrate upon quality, low production costs, and efficient salesmanship.

IN August last, a gentleman who desired to remain anonymous, called at the London Hospital and stated that he wished to make a gift for some charitable purpose and asked advice as to the best way of doing so. Eventually it was agreed that most good could be done by endowing medical research in connexion with the Hospital. It was explained to the donor that such research is badly handicapped in that there is little possibility of a man taking it up as a life-work unless he has means of his own. Finally a trust deed was agreed on stating that the income should be spent in salaries, and not on 'bricks and mortar' or laboratory equipment, which it was thought the Hospital itself ought to provide. Later, the donor presented 50,000*l*. and the fund has been named the Freedom Research Fund. Its working is managed by a small committee consisting of a nominee of the donor, the head of the Clinical Laboratory, and the House Governor of the Hospital. Provision has been made for an annual scholarship in pathology of 100*l*. open to students of Oxford and Cambridge, a research studentship of 400*l*. a year for three years, to which Mr. L. Hewitt has been appointed, and the remainder of the fund between two senior pathologists to enable them to devote their whole time to research. Dr. S. P. Bedson, of the Lister Institute, and Dr. W. Howard Florey, of the University of Cambridge, have been appointed for this latter purpose. These workers will have the advantages that they will be engaged entirely on research work, but shoulder to shoulder with the Hospital Laboratory staff doing the routine investigation work of the Hospital; they will be in touch with the clinical work of the Hospital and especially with the Medical Unit; and they will be working in a centre where unlimited clinical material is available. It is hoped to enlarge this fund.

M. H. PARODI, the chief engineer of the Paris-Orleans Railway Company, read an interesting paper on railway electrification to the Institution of Electrical Engineers on February 18. Since the War, the development of electric railways and the suburban supply of electricity has been very rapid in France. The scheme on which M. Parodi is working is to substitute electric for steam traction on a line where the traffic is very heavy, and to provide a power transmission system for all the districts through which the railway passes. In France, the electrification of the railways forms part of a general network for power supply. This network will be built up gradually by linking together many of the existing distribution systems. The policy adopted by France of co-ordinating the supply of electric power to the railways with the general supply of power is different from that adopted by Germany, Switzerland, Austria and other countries, where the electric traction problem is considered without reference to power supply. If the power transmission lines were to follow the railway from Paris to Toulouse through Orleans, Limoges and Brive, then the great steam power stations of the Paris district could be linked with the hydro-electric stations of the Central Plateau and the Pyrenees. From the electrical point of view the use of very high voltages presents many advantages. Such lines are affected very little if at all by atmospheric phenomena. Whilst the power that can be transmitted varies as the square of the voltage, the first cost only varies directly as the voltage. With the pressure of 150 kilovolts now in use, it is possible to transmit economically 50,000 kilowatts from the Central Plateau to Paris, a distance of about 280 miles. It will be of interest to see how the relative cost of generating electricity by water power and by steam in France works out in practice.

DR. C. HAGBERG WRIGHT took for the subject of his discourse delivered at the Royal Institution on February 26 a remarkable but little-known personality in the literary history of France, the Sieur Nicolas Fabri de Peiresc, a gentleman of France, in the early seventeenth century. Peiresc, whose fame has suffered from the modesty of his character, was satisfied to minister to the needs of his brother authors and scientific workers, without desiring personal reward. Accordingly he gave, lent and borrowed books for his friends, and kept two bookbinders and an engraver continually employed. He had also in his household an astronomer named Garrat, having built an observatory where he carried on astronomical observations by the aid of a telescope constructed by Galileo himself. His studies took a wide range, including astronomy, numismatics, ancient inscriptions and monuments, optics, music and horticulture. Without being, strictly speaking, a pioneer in any of these subjects, it was through his efforts that many aids to science were brought into France, and also valuable manuscripts obtained from Egypt, Cyprus and Syria. Through him the microscope found its way from Holland, where it was invented, into France. In optics his observations were in advance of his contemporaries, and he is said to have been the first to observe the phenomena of negative and positive after-images. In astronomy he co-operated with Gassendi during several years. Towards the end of Peiresc's comparatively short life his love of botany and horticulture became his supreme pleasure. His correspondence with l'Escluse, the great Dutch botanist, remains to testify to his ardour in this direction. Incidentally, Peiresc is believed to have introduced the tulip into France, after it had been brought from Constantinople by an Austrian diplomat, named Busbecq, in 1562, and by l'Escluse carried to Holland, whence Peiresc obtained it. After fifty-seven years of untiring activities Peiresc succumbed to the ill-health which had accompanied him through life.

DR. H. T. CALVERT, of the Ministry of Health, delivered a Chadwick Public Lecture on February 26, taking as his subject, "The Activated Sludge Process of Sewage Treatment." He stated that no aspect of the sewage purification problem has been so much discussed since the War. The process has been developed from the older methods including land irrigation and treatment in contact beds or percolating filters; the activated sludge is obtained from the sewage itself by means of aeration and is then used for the purification of further quantities of sewage. Various methods of applying the process have been invented, all of which aim at oxidising the organic matter of sewage, by means of air and micro-organisms, in the most efficient manner and at the lowest possible cost. As compared with ordinary sludge, activated sludge is of higher manurial value, but the difficulty of removing the water which adheres to the sludge will no doubt stand in the way of a general adoption of the process and a full utilisation of activated sludge as a manure. The capital expenditure to which local authorities in Great Britain are already committed for applying the activated sludge process amounts to approximately one million pounds sterling and a larger amount has already been spent on the process in the United States. Dr. Calvert concluded by asking for more extended scientific investigations of the process, with the view of furnishing the necessary information for the design of further works.

SOME interesting suggestions are put forward by a correspondent in the *Times* of February 24, relative to the origin of the type of the Amenhetep temple at Beisan in Palestine. This temple was one of four of different dates, three being superimposed, discovered during 1925 by the expedition of the University Museum, Philadelphia. It belongs to the Amarna period, in itself a matter of considerable interest, and is very similar in style to the tomb chapels found at El-Amarna. At the same time the cult objects found in the temples of Seti I. and Rameses II. at Beisan show a resemblance to cult objects from the temple of Ishtar at Assur, in which the cult-room is not so much Assyrian as comparable in type with that of temples at Bogazkeui, the Hittite capital. The existence of an Assyrian colony in Anatolia at the end of the third millennium B.C. appears to supply a link, and the suggestion is thrown out that the temple of Amenhetep at Beisan, which has a certain similarity to the cult-room, may have been built after the model of a Hittite temple and itself have influenced the form of the Amarna tomb-chapels. This latter somewhat unexpected and, some may think, improbable suggestion will give an added interest to the results of further excavation.

DR. T. W. GANN, in the course of a series of articles contributed to the *Morning Post* in the issues of February 22 and the two succeeding days, chronicles one of the most important finds of recent years for the history and chronology of the Maya in Central America. He has found in the Territory of Quintana Roo, Yucatan, a stele with an inscription, which contains the Maya Initial Series Date, 9.8.0.0.0.5. Ahan, 3 Chen, or October 26, A.D. 333. This date is more than 300 years earlier than that appearing on the oldest of the stelæ previously found, and is one of only four such Initial Series Dates found among all the Maya ruins in Yucatan. In view of the importance of fixing the date when the Maya first established themselves in Yucatan, this discovery, as Dr. Gann points out, "may cause a complete reversion of the ideas generally held as to their first immigration into this peninsula and their foundation of what is known as the New Empire."

THE forty-eighth annual general meeting of the Institute of Chemistry was held on March 1, Prof. G. G. Henderson, president, in the chair. The Meldola Medal was presented to Dr. Henry Phillips. In moving the adoption of the annual report, which showed that the roll of the Institute now numbers nearly 5000 fellows and associates, the president referred to the decrease in unemployment in the profession, and mentioned that there are indications that not only those industries which are strictly chemical in character but many others are also finding that well-trained research and analytical chemists are necessary to combat the effects of industrial depression. To some extent, the situation has been relieved by members passing into other work and also owing to the fact that the output of chemists from the universities has been less during the last two or three years. The Committee of the Institute has been concerned with matters affecting fertilisers and feeding stuffs, in which valuable assistance was rendered to the Ministry of Agriculture and Fisheries; with the Royal Commission on National Health Insurance, on which the Council represented the views of public analysts responsible for the examination of drugs under the Sale of Food and Drugs Acts; with the Labour Party on the subject of Government scientific publications; and also with the Director of Public Prosecutions. The local sections of the Institute have become increasingly active. The problem of seeking statutory powers of registration for professional, consulting and analytical chemists has been under the earnest consideration of the Council. Prof. G. G. Henderson was re-elected president of the Institute.

THE second Italian National Congress of Pure and Applied Chemistry, to be held in Palermo, opens with a reception in the Botanic Garden on May 22 next and closes on June 2. Many well-known chemists have already made known their intention to be present, and a large attendance is expected. In addition to meetings of the Congress and of its various sections, and visits to works and to places of interest in the neighbourhood of Palermo, the provisional programme comprises a five-days' tour, during which opportunities will be afforded to see Girgenti and its temples, mines and industrial establishments, Syracuse, the asphalt deposits of Ragusa, Catania and its sulphur refineries, Etna, Taormina, Messina, etc. The meetings of the Congress are divided into three groups, dealing with (1) questions of scientific or industrial importance, (2) communications to several sections jointly, and (3) papers and discussions relating to different chemical industries and to branches of pure chemistry. Any chemist wishing to read a paper before Group 1 of the Congress is requested to furnish the General Secretary, Via IV Novembre 154, Rome 1, with a summary of his communication not later than April 30, while for Group 3 the Secretary should be informed of the title by April 30 and should be supplied with the text, together with a résumé, by May 10. Fifteen minutes will be allotted to the reading of each paper, and not more than forty minutes to a discussion of general interest.

THE Wilde memorial lecture of the Manchester Literary and Philosophical Society is to be delivered by Prof. G Elliot Smith on "Brains of Apes and Men," at 4 o'clock on Tuesday, March 9.

THE recent issue of the index parts of the Physics and Electrical Engineering Sections of Volume 28 completes *Science Abstracts* for 1925. The Physics Section has viii + 1045 pages, of which 41 are devoted to a name index, and 98 to a subject index. The number of abstracts of papers is 2808, and their average length 0·32 of a page. The Electrical Engineering Section has viii + 692 pages, with 23 for name and 51 for subject indexes, and 1811 abstracts of average length 0·34 of a page. As compared with last year the Physics Section has decreased by nearly 200 pages, and the Electrical Engineering Section increased by 40 pages. In both sections there has been a decrease in the average length of an abstract, which in the previous year was 0·36 of a page. So far as we have been able to judge during our use of the abstracts, this decrease of length has not been accompanied by a decrease of value, but is rather a proof of the increased skill of the abstracting staff. To the regular user of *Science Abstracts*, the attitude of the physicist or electrical engineer who regards it as unnecessary is difficult to understand—it seems like prospecting without a pick and shovel.

THE second issue of the *Journal of the Royal Technical College* (Glasgow) is of interest from more than one point of view. In the first place, it demonstrates the high standard of research which is being carried out in the College, and, secondly, it represents a serious attempt to add another to the list of well-recognised periodicals in which research work may find the light. The fifteen original pieces of work published are very much more than merely students' contributions, and the names of Profs. Caven, Wilson, Andrew, Kerr, Mellanby and Ellis are all found among the contributors to this single number; this is in addition to other work they may have published elsewhere. The general standard of papers is undoubtedly high. As an indication of the ground covered it is sufficient to enumerate the individual contributions: The magnetic properties of permalloy, the measurement of rapidly fluctuating temperatures; the production of hydrogen by steam in a hot boiler tube; the presence of air in pure and alkaline water; the pseudo-alums; additions to our knowledge of azoxy compounds, reactions of semicarbazides; some acyl derivatives of hydrazine; the separation of the components of petroleum; the crystalline structure of metals; specific volume determinations of carbon and chromium steels; the evaporative condenser (a paper of 38 pages); a note on blade stresses in nozzle controlled turbines, compression losses in divergent jets, and an investigation into the cause of the blackening of the sand in parts of the Clyde estuary. The issue, like the previous one, is excellently printed and illustrated. Every one interested in the progress of science, especially perhaps in its more practical applications, will join in wishing this, the latest among the scientific journals devoted to the publication of the results of original work, a very long and prosperous career.

THE Barclay Memorial Medal for 1925 of the Asiatic Society of Bengal has been awarded to Lieut.-Col. J. Stephenson, lecturer in natural history in the University of Edinburgh, in recognition of his work as a biologist and as the founder of the School of Zoology in Lahore.

THE ninth Silvanus Thompson memorial lecture of the Röntgen Society will be given on Tuesday, March 30, in the Barnes Hall of the Royal Society of Medicine, by Sir John Thomson-Walker, who will take as his subject "Radiology in Urinary Surgery."

DURING the last five or six years there has been a slight renewal of activity in the well-known earthquake centre at Comrie in Perthshire, and a shock was recorded on February 21 at 4.24 A.M. The tremor was evidently slight, lasted only a few seconds, and was accompanied by the usual sound resembling muffled thunder or an explosion.

AT the annual meeting of the Geological Society of London, on Friday, February 19, the following officers were elected: *President*, Dr. F. A. Bather; *Vice-Presidents*, Dr. J. W. Evans, Sir Thomas Holland, Mr. H. W. Monckton, Sir Arthur Smith Woodward; *Secretaries*, Mr. W. Campbell Smith, Dr. J. A. Douglas; *Foreign Secretary*, Prof. J. E. Marr; *Treasurer*, Mr. R. S. Herries.

THE second Italian National Congress of Pure and Applied Chemistry, to be held in Palermo on May 22-June 2 next, will be made the occasion of the celebration of the centenary of the birth of Stanislao Cannizzaro, which occurred in Palermo on July 13, 1826. On May 24, the body of the great Italian chemist is to be conveyed to the Pantheon, and this ceremony will be followed by the inauguration of the monument erected to his memory.

DURING the month of March, Miss Elizabeth Keith will exhibit at the Royal Anthropological Institute a number of her water-colour sketches of natives of Japan, Korea, China, and the Philippines and of the Ainu. Although in some cases, especially as regards the natives of the Philippines, it is permissible to doubt the purity of some of her types, Miss Keith has on the whole been happy in her choice of subjects, the Ainu, not unnaturally, being the most interesting and possibly the most picturesque. Admission to the exhibition is free.

IT is interesting to note that Sir John Marshall, in his further account of explorations on prehistoric sites in the Punjab and Sind in the *Times* of Feb. 26, records the occurrence of a similar chalcolithic culture at Nal, some 250 miles south of Quetta, in the Jhalawar country of Baluchistan. Polychrome pottery, analogous to that found at Mohenjo-Daro and Harappa, as well as copper implements, grindstones, and other small objects, have been found in a burial-ground in which the dead are buried in sun-dried brick graves or directly in the ground. This marks a distinction from the Mohenjo-Daro and Harappa sites, where at this early period the dead were cremated. The complete skeletons found at Mohenjo-Daro, it is said, are probably to be attributed to the beginning of the Christian era.

WE learn from a recent issue of the *Weekly News Bulletin* of the U.S.S.R. Society of Cultural Relations with Foreign Countries, that at the first meeting of the Academy of Sciences at Leningrad in 1926 a number of new honorary members were elected. The list includes: Prof. A. Svante Arrhenius (Stockholm); Prof. H. A. Lorentz (Leyden); Prof. Max Planck (Berlin); and Prof. Vito Volterro (Rome). The list of correspondents elected includes: Prof. A. Sommerfeld (Munich); Prof. Emil Abderhalden (Halle), Prof. G. Urbain (Paris).

AN Easter tour to the Valley of the Dordogne, lasting from April 1 until April 15, has been arranged by Prof. Patrick Geddes. The headquarters of the party will be Les Eyzies and, afterwards, at Domme. From Les Eyzies visits will be paid to all the more important caves and sites of prehistoric discovery in the neighbourhood. By permission of the Ministry of Public Instruction, M. Peyrony, Conservateur du Musée Archéologique, the well-known French archæologist, will act as guide and will also demonstrate the important collections in his museum. From Domme a series of daily excursions devoted to the regional survey of the geography and history of the most attractive part of the Dordogne Valley will be conducted by M. Paul Reclus, formerly professor of geography at Brussels. Full particulars of the tour may be obtained from Miss Jowett, 152 Abbey House, Victoria Street, London, S.W.1.

APPLICATIONS are invited for the following appointments, on or before the date mentioned:—A professor of mechanical and electrical engineering at the Artillery College, Woolwich—The Assistant Commandant, Artillery College, Red Barracks, Woolwich, S.E.18. A research mycologist in the Department of Agricultural and Horticultural Research of the University of Bristol, Long Ashton—The Registrar of the University (March 22).

Our Astronomical Column.

A LARGE SUNSPOT.—A spot now on the sun's disc has been seen with the naked eye, thus making the fifth of its kind to be recorded since the beginning of the year. The spot is of recent origin, as no trace of it was seen on February 9, when its position would have been near to the receding west limb of the sun. Its shape is somewhat irregular, and its size is about half that of the great spot of last January. Further particulars are as follows:

No.	Date on Disc.	Central Meridian Passage.	Latitude.	Area
5	Feb. 25-(Mar. 10)	March 3·6	27° S.	1/600

(Area expresses the proportion covered of the sun's hemisphere.)

RECURRENCE OF MAGNETIC 'STORM.'—On February 23, a considerable magnetic disturbance commenced at 16¼ hr., reached its greatest intensity between 13 hr. and 19 hr. on February 24, and died away by about 5 hr. on the following morning. The greatest range shown by the declination magnet throughout the disturbance was a little more than 1°. Bright moonlight probably prevented the observation of aurora, which would be a likely phenomenon on the nights of February 23 and 24. The interval between the commencement of this magnetic storm and the preceding one on January 26 is 28·0 days. The sunspot disturbance, with which it is presumably related, is in solar latitude 22° (see NATURE, Feb. 6, p. 208). The time taken for a spot at this latitude to make one complete rotation relative to the earth is, on the average, 27·6 days.

As evidence of the existence of a relationship between sunspots and magnetic disturbances, Mr. E. W. Maunder showed from the Greenwich magnetic and sunspot data that the latter frequently recur at intervals of about 27 days, corresponding to the average period of the sun's rotation relative to the earth as given by sunspots (*Monthly Notices R A S.* 65, 2-34, 1904). The last two 'storms' provide an example of such a recurrence.

THE SPECTRUM OF THE RECENT AURORA.—In a letter received from Prof. L. Vegard, Universitets Fysiske Institut, Oslo, an account is given of the aurora of January 26, which appeared at the time of the magnetic storm noted in NATURE for February 6. Prof. Vegard writes that the striking feature of this aurora was its intense red colour, which spectroscopic analysis showed was mainly due to one single sharp line in the red, about $\lambda = 6323$ Å.U. Spectrograms taken at Oslo and Tromso also showed the characteristic auroral spectrum consisting of the 'auroral line,' 5577 Å.U., and the negative bands of nitrogen. The prominent red line has been recorded on two previous occasions at Tromso in 1923–24, and its mean wave-length deduced from the three observations is 6322·4 Å. Prof. Vegard states that the line, which is of the same character as the 'auroral line,' cannot be due either to hydrogen, helium, oxygen, or the ordinary spectrum of gaseous nitrogen. When, however, solid nitrogen is bombarded with cathode rays, two pairs of narrow bands (N_1N_2) and (N_3N_4) appear in the red and green parts of the spectrum. The relative intensities and character of these bands vary considerably with the magnitude of the nitrogen particles, the properties of the electric discharge, and when an inert gas, such as neon, is introduced (see also NATURE, May 1924, p. 716, for Prof. Vegard's account of his investigations of the auroral spectrum). From these laboratory experiments, Prof. Vegard thinks that this red line, 6323, is to be regarded as the limiting aspect of the band N_2, just as he considers the auroral line, 5577, to be the limiting aspect of N_1. Moreover, the study both of the luminescence spectra of solidified gases and the oscillation band series suggests to him that the changes of colour so frequently observed in auroræ may result from a transformation of the spectrum due to oscillations.

Another letter, received from the Chief of the Polish Maritime Station at Danzig, gives observations of the same aurora seen at that place and at the Hel peninsula. The colour is described as varying from brick-red to dark carmine and its brightness as being very variable.

Attention may be directed to two other recent contributions to the problem of the auroral spectrum appearing in *Proc. R S.*, Series A. vol. 106, p. 117 and p. 138, by Lord Rayleigh, and Prof. McLennan and Dr. Shrum, respectively.

COMETS.—Ensor's comet is now well placed for observation in the morning; it is moving north so rapidly that it will soon be observable throughout the night. The following ephemeris is for 6^h A.M.:

	R.A.	N. Decl.	log r.	log Δ
Mar 4.	$21^h\ 2^m\ 48^s$	21° 4′	9·8124	9·9643
8.	21 13 23	30 33	9·8661	9·9481
12.	21 28 14	40 13	9·9134	9·9419
16.	21 48 56	49 36	9·9552	9·9466
20.	22 17 48	58 12	9·9928	9·9616

Its naked eye visibility during this period is doubtful, but it will probably be an easy telescopic object. On the morning of March 8 it will be ¼° east of Zeta Cygni, on March 14 1¼° east of Rho Cygni. It then passes through Cepheus and the northern part of Cassiopeia.

Blathwayt's comet has grown fainter, but should still be within reach of moderate apertures. The following ephemeris is for 0^h:

	R.A.	N. Decl.	log r	log Δ
Mar 4.	$5^h\ 53^m\ 14^s$	42° 47′	0·2055	0·0123
8.	5 41 24	43 50	0·2140	0·0620
12.	5 32 35	44 30	0·2225	0·1061
16.	5 26 1	45 3	0·2312	0·1462

The comet is in Auriga, moving nearly parallel to the line joining Beta to Alpha.

Tuttle's comet may be visible with moderate apertures when the moon is absent. The ephemeris for 0^h is:

	R.A.	N. Decl.	log r.	log Δ.
Mar 3.	$1^h\ 21{\cdot}7^m$	30° 43′	0·1222	0·2249
11.	1 52 1	28 25	0·0991	0·2226
19.	2 22·2	25 49	0·0769	0·2212

Prof. A. Dubiago gives the following hyperbolic elements for Van Biesbroeck's comet, based on observations on Nov. 19, Dec. 4 and 21, Jan. 12.

$$\begin{array}{ll} T & 1925\ \text{Oct.}\ 3{\cdot}00066\ \text{U.T.} \\ \omega & 106^\circ\ 25'\ 13{\cdot}0'' \\ \Omega & 334\ \ 34\ \ 29{\cdot}9 \\ i & \ \ 49\ \ 10\ \ 38{\cdot}4 \end{array} \Bigg\}\ 1925{\cdot}0$$

$\log q$ 0·19500,

RECENT STUDIES OF PITHECANTHROPUS. — In *Natural History*, the journal of the American Museum of Natural History, Vol. 25, No. 6, Dr. J. H. M'Gregor summarises recent views on *Pithecanthropus erectus*, but in addition contributes to the discussion of the place of these remains in our knowledge of the phylogeny of man the conclusions at which he himself has arrived as the result of first-hand study of the bones themselves and of Dr. Dubois' endocranial cast. Owing to erosion of the outer bone by the action of sulphuric acid, casts of the calvarium give an erroneous impression which can only be corrected by examination of the actual bones. 3·5 millimetres and more must be added to the maximum length, making it 184 mm. Further, the nuchal surface of the occiput to which the powerful neck muscles were attached has also suffered. The original occipital slope was therefore more vertical and consequently more ape-like than the cast. The corrected breadth measurement, allowing for erosion, gives an index of 71·5. In the endocranial cast both the development of the so-called Broca's convolution and the marked expansion of the middle temporal convolution support the view that Pithecanthropus could produce and appreciate articulate speech. In a reconstruction of the size and form of the brain made by Dr. M'Gregor, the hominoid features outweighed the pithecoid very decidedly and gave a volume of 940 cc. The general brain form is more like the gibbon than the gorilla, though in convolution it is more like the latter. In both size and form, however, the brain is distinctly closer to man than that of any ape.

THE SIGNIFICANCE OF THE CHARACTER OF THE HAIR IN MAN.—Dr. Fritz Sarasin has contributed a study of changes in the character of the hair in Melanesian and African children to *L'Anthropologie*, T. 35, pts. 5-6, in which he arrives at conclusions of no small importance in relation to the question of the significance of hair as a criterion of race. It has been stated by Martin that the form of hair characteristic of the different races is already to be observed in the newly-born, and the same or similar statements have been made by other anthropologists. Dr. Sarasin is unable to endorse this view as a result of his observations among the Melanesians and Africans. Among New Caledonians, infants up to the age of a year or a year and a half have almost straight or slightly wavy hair, of brown, light brown, or even blond. It does not begin to change until about five years, and does not become completely frizzy like that of an adult until about six years, when it is still slightly lighter in colour. This observation is supported by the records of observers in the New Hebrides (Speiser, Heim), in Africa (Collignon, Frédéric, Junod, Borel), and among the negroes of the United States (Schultz). Among negroes, however, the hair is black and not lighter in colour, and the change in form takes place rather earlier. It follows that frizzy hair must be considered a secondary character in man. No anthropoid or other ape has frizzy hair. Thus it must have been acquired at a later geological epoch, the straight or wavy hair being the primary character. Further, if it is a secondary character, it must be possible for it to have been acquired by the different races of which it is now a character at different times and in different ways. Frizzy hair, therefore, cannot be regarded as a possible basis for racial classification.

PREDICTIONS OF A MACKEREL FISHERY FROM SALINITY OBSERVATIONS.—In No. 8 *Medd. fra Komm. f. Havundersøg. Ser. Fiskeri*, Bind 7, 1925, Copenhagen, Dr. A. C. Johansen deals with the occurrence of mackerel in the Kattegat and adjacent parts of the Skagerak. In the waters of the Kattegat and Belt Sea, two layers occur usually, a surface layer of relatively low salinity, and a lower layer with relatively high salinity. This stratification is due in the main to the outflow of relatively fresh water from the Baltic, and the inflow of relatively salt water from the Skagerak. In the upper layer, to a depth of about 10 m. to 25 m., the resulting current is directed towards the Skagerak and the North Sea, while in the lower layer it is towards the Baltic. Johansen advances evidence to show that there is a connexion between yearly catches of mackerel in the Kattegat, a strong ingoing current in the lower layer in April and May indicated by a high salinity, and a low temperature of the surface waters in June. He concludes that a prediction with a certain degree of probability whether it will be a good or bad mackerel year can be given so soon as salinity observations in March and April are to hand, or about one or two months before the fishery in the Kattegat begins. Dr. Johansen adds a footnote to the effect that predictions will be published in *Dansk Fiskeritidende*.

ENCYSTMENT IN DIDINIUM.—C. Dale Beers records (*Proc. Nat. Acad. Sci. U.S.A.*, vol. 11, Sept. 1925) the results of studies on encystment in the ciliate *Didinium nasutum* with the view of ascertaining the cause of the conflicting conclusions reached by Calkins and by Mast. Calkins picked out from each of ten pure lines of this ciliate a single individual and supplied it with nine specimens of Paramæcium daily as food. As generations passed the fission-rate gradually decreased and the encystment rate increased, the latter reaching 100 per cent. in the 131st generation. Calkins concluded that in Didinium the passage of generations results in diminished vitality and ultimately in encystment with nuclear reorganisation and rejuvenescence, and that there are two types of encystment, one which protects against environmental adversity, and the other which occurs periodically and independently of the environment and results in rejuvenescence. Mast's experiments differed from those of Calkins in that at each isolation of Didinium, he placed with this ciliate enough Paramæcium to ensure a surplus of food, and he found no evidence to indicate that encystment occurs periodically. The present author has carried out two series of experiments on Didinium descended from one individual—one series of four lines was cultivated according to the procedure of Calkins, *i.e.* each Didinium was supplied daily with nine Paramæcia; the second series of four lines was supplied, as in Mast's investigations, with sufficient food to ensure a surplus. Except for this difference the two series were kept under the same conditions. The first series behaved like those in Calkins' experiments and the second like those of Mast. The encystment in the first series was due to the unfavourable condition—lack of food. The mere passage of generations does not result in encystment or in decreased fission-rate, provided the environment is favourable. The evidence indicates that all the cysts of Didinium are of one type—protection cysts.

EFFECT OF ULTRA-VIOLET RAYS ON THE GERMICIDAL ACTION OF THE BLOOD.—Colebrook, Hill, and Eidinow showed that when the skin is exposed to sources of ultra-violet rays the power of the blood to kill bacteria is greatly increased when tested *in vitro*—by so much as 65 per cent. in the rabbit and 17 per cent in man. Further work (A. Eidinow, *Brit. Journ. of Radiology* [B.I.R. Section], vol. 31, No. 306, 1926, p. 35) has shown that this increased germicidal power of the blood is evoked only when the rays produce erythema (reddening) of the skin—preferably a mild erythema that disappears within twenty-four hours. An excessive exposure of the skin to the sun's rays may cause a diminution of the bactericidal power of the blood. It is only ultra-violet rays shorter than 3100 Å U. which produce erythema and likewise increase bactericidal function of the blood, and those derived from the mercury vapour lamp, the carbon arc, and sun's rays are equally efficient. The mechanism of the action is uncertain, for there is no experimental evidence to support the view that the irradiated skin cells form a bactericidal substance If an animal is injected with bacteria so as to cause a septicæmia or blood-poisoning, the natural bactericidal power of the blood falls to a very low degree, and irradiation of the skin with ultra-violet rays during this stage does not increase the bactericidal power of the blood, so that acute infections of this kind cannot be treated by these means. Direct exposure *in vitro* of defibrinated blood to ultra-violet rays destroys such bactericidal power as it may possess, but injection of 10-20 cc. of this irradiated blood into a rabbit results in a marked rise in the bactericidal power of the blood of the animal after a latent period of two hours. The phenomenon appears to be due to some effect on the corpuscles, for it is not obtained with irradiated blood-serum without corpuscles.

A FLORA OF UTAH AND NEVADA.—Volume 25 of Contributions from the United States National Herbarium is a flora of Utah and Nevada, by Ivor Tidestrom. This area lies wholly within the arid region, but is very diversified in character with high mountains separated by dry desert valleys or by tablelands The flowering plants and ferns are treated systematically, some 3700 species being included, with keys to the species and larger groups. In an interesting introduction the author draws a striking parallel between topography and vegetation of this corner of the United States and the Iberian peninsula in Europe. H. L. Shantz gives a brief summary of the main characteristics of the chief plant communities from the point of view of the ecologist, whilst Arthur W. Sampson deals with the environment of the flora of the alpine regions and foothills Within this region the flora typical of the western United States meets the flora typical of northern Mexico, the line of demarcation being described by Tidestrom as conspicuous in south-western Utah and southern Nevada, where it coincides with the northern limit of *Covillia tridentata*, the creosote-bush.

TRAUMATROPIC CURVATURES IN PLANTS.—This conception of curvature in plants as resulting from the "stimulus" of a wound is perhaps of doubtful validity, and Adolph Beyer has recently completed an examination of the subject (*Biologisches Zentralblatt*, vol. 45, pt. 12), which leads him to an alternative interpretation Such curvatures, he thinks, should be explained as due rather to an interference with the normal nutritional correlation as a result of the wound. He thus explains curvatures in seedling hypocotyls, coleoptiles, and roots as due to a disturbance of one of two correlations, namely: (i.) Growth-promoting substances moving from the apex of the coleoptile, or the epicotyl in the case of the Helianthus seedling; (ii.) food supplies moving to growing tissue from regions of storage.

THE OLD RED SANDSTONE FLORA OF SCOTLAND.—Prof. W. H. Lang contributes an interesting paper to the *Transactions of the Royal Society of Edinburgh* (vol. 54, Pt. 2, No. 2), in which he continues the important studies which he commenced with the late Dr. R. Kidston. He has studied the plant-remains from the fish-beds of Cromarty and finds evidence of the existence of a considerable bulk of vegetation of varied character. By extracting the remains of spores and sporangia from the rock, he has recognised nine distinct types of spores and two types of sporangia. Some of the spores have a very characteristic form and ornamentation, but the plants which bore them are as yet unknown, and they indicate that several more plants of the epoch remain to be discovered. The other plant remains are fragmentary, but under Dr Lang's careful treatment have yielded valuable results. He has found that Thursophyton had circinate buds like Psilophyton. The genus Hostimella has received further elucidation, and two new species with characteristic sporangia have been described. One, *H. pinnata*, shows a series of incurved pinna-like branch systems with sporangia at their tips. No suggestion is as yet made as to the systematic position of these forms, but their remoteness from the Lycopodiales is pointed out. To a less cautious observer they suggest a resemblance to some of the much dissected fronds of the Lower Carboniferous pteridosperms and ferns. Another organism described, *Hostimella racemosa*, is a sporangium bearing branch system; it was derived from the Stromness beds. This is a remarkable structure consisting of an axis bearing sporangium-like organs on either side, each sporangium being surrounded by a zone where the rock is stained a darker colour forming a sort of halo. There is no evidence as to the type of plant on which these branches were borne and it is provisionally placed in the genus Hostimella, but it is clear that this artificial genus, while possessing little vegetative differentiation, had reproductive organs of a varied character. The whole work is a valuable contribution to our scanty knowledge of the earliest known land flora of the world.

MOUNTAIN BUILDING AND IGNEOUS ACTION.—In the *Proc. Am. Phil. Soc.* vol. 64, 1925, p. 283, Prof. R. A. Daly returns to his geological exploration of the possibilities arising from the assumption that the Taylor-Wegener hypothesis of continental drift is correct. He conceives that the moving continents slide on a substratum of hot basaltic glass which, though rigid to stresses of short periods, is extremely weak. Mountain chains are then explained as structures that have been compressed on the down-stream side of continental "landslides." Upstream, breaking tensions are necessarily developed, and mobile fractions of the substratum are forced up the abyssal fissures, the general type of magma generated being basaltic. Downstream, the granitic crust beneath a geosyncline is overridden by the sliding foreland, and part of it sinks down into the underlying basalt which is thus displaced, and tends to erupt along the soles of thrust-planes. The sunken crust then melts, and gives rise to secondary magmas that invade the crumpled sediments as batholiths and stocks with all their attendant dykes and lavas. The rise of magma is aided by gas pressure, the juvenile gases acting as fluxes in the development of volcanoes of the central type. A combination of the Joly and Wegener hypotheses may make this or some similar scheme workable, but it is difficult to believe in the glassy substratum, for seismology persistently fails to provide any evidence for the existence of a basaltic layer beneath the continents. A rock-layer of density about 3·4 is indicated, and this may be eclogite, since the geological evidence is conclusively in favour of a basaltic composition. The possibilities thus seem to be eclogite during periods of solidity and basaltic magma during epochs of fusion, basaltic glass being completely ruled out.

A Giant Crater in Alaska.—During recent exploration of the country west of the Aleutian Mts. by a United States geological survey party, a gigantic crater was discovered, which, with its associated features, closes what was supposed to be a wide gap in the volcanic line of the Alaska Peninsula. Mr. W. R. Smith gives an interesting account of the crater in Prof. Paper 132-J of the U.S. Geological Survey, 1925. The rim is nearly circular and has an average diameter of more than six miles. The area of the crater thus exceeds that of Crater Lake, Oregon (5¾ miles in diameter), but is only about half the area of the craters of Ngorongoro in East Africa and Aso-san in Japan. These three craters are all examples of the type known as calderas and are due to subsidence. The newly discovered crater, named Aniakchak Crater (after the river that rises within it), belongs, however, to the explosive type, of which it is now the largest example known, Katmai Crater, also in Alaska, having previously held the record with a diameter of three miles. If the volcano had originally possessed a low cone, then about 15 cubic miles of material must have been blown away. Much of this can be accounted for by the great spreads of volcanic ash already known to the east and south. Within the crater is a large truncated cinder-cone, rising to 2200 feet above Surprise Lake, which occupies part of the north-eastern floor of the crater. The volcanic formations lie on a basement of Upper Jurassic sediments, and the inner wall of the crater is made up of layers of pink and black lava—probably obsidian—with quartz-diorite below. Black obsidian is also found ten miles away, though exposures of lava flows are rare owing to the thick covering of the surrounding country by fragments of glassy lava, pumice, and ash. The volcano is now completely quiescent, no fumerolic activity having been detected.

Currents in the Upper Air.—The Meteorological Office, Air Ministry, in Professional Notes, No. 42 (London: H.M. Stationery Office, 1925, price 1*s.* 6*d.* net), gives the result of an "Investigation of the Winds in the Upper Air from Information regarding the Place of Fall of Pilot Balloons and the Distribution of Pressure," by Mr. J. Durward. This note discusses the horizontal movement of pilot balloons in relation to the distribution of pressure. The data used are obtained from post cards, on which the date, place, and time of origin are entered, attached to the pilot balloons. The finder of the balloon is requested to return the card after entering the place and time of finding. During 1923 more than 1000 cards were returned. The results throw some light on the direction of winds at high levels, but the method is attended by so many uncertainties that it is, on the whole, inferior to the careful observation of high clouds, although it is practicable in all weathers.

Variations in Radio Signals.—In broadcasting it is well known that there are great variations in the quality of the reception. These variations are due to many factors, including sunlight, temperature, barometric pressure, humidity and human agencies. As they occur not only from season to season, but even from hour to hour, they are far too complex to permit of a simple analysis. The only satisfactory method of attacking this problem is the statistical method, namely, to analyse similar observations taken over specified areas by a number of competent observers during a considerable period of time. A test of this nature was organised by the Bureau of Standards over a period of a year (1922–1923). Mr. C. M. Jansky has analysed the results in Paper No. 297 of the Bureau of Standards. The results shown by observations made of KDKA, the transmitting station of the Westinghouse Co. at Pittsburgh, prove that "fading" is most pronounced in September and October, and least in February and April. The atmospherics were worst in August and September, and least in February and March. It has sometimes been stated that signals from distant stations are often of greater intensity than signals from stations of similar power but situated much nearer to the observer. The results obtained by two entirely different sets of observers on two different transmitting stations verify this. It is clearly indicated that somewhere between 100 and 200 miles the signals are less satisfactory than the signals received from much more distant stations. From the scientific point of view this is of importance.

Structure of Graphite.—In No. 3 of the *Scientific Papers of the Institute of Physical and Chemical Research, Tokyo*, G. Asahara has shown by means of measurements of the diffraction of X-rays that, however finely powdered, graphite possesses a crystalline structure. In the case of thirty-four different forms examined, amorphous carbon and graphite are essentially identical.

Separation of Indium.—Reprint No. 5 from the *Scientific Papers of the Institute of Physical and Chemical Research, Tokyo*, is a description of the detection and separation of indium. A method was devised of precipitating indium by means of ammonium sulphide from a dilute solution acidified with sulphuric acid, after the addition of a small amount of tartaric acid and neutralisation with ammonia. This proved satisfactory when tested with mixtures of several kinds.

"Knock" in Internal Combustion Engines.—Report No. 979 (E. 15) of the Aeronautical Research Committee (London: H.M.S.O., price 2*s.* 6*d.* net) deals with closed vessel explosions of mixtures of air and liquid fuel (petrol, hexane, and benzene) over a wide range of mixture strength, initial temperature, and initial pressure. Attention was particularly directed to the production of detonation in internal combustion engines. The conclusions are too numerous to summarise, but a few points may be mentioned. At 100° C. the air-fuel ratio for maximum explosion pressure is considerably less than that required for complete combustion. Rich mixtures of all three fuels give rise to a knock, the intensity of which increases with decrease in the air-fuel ratio and is apparently preceded by high frequency vibrations. Raising the temperature sometimes eliminates the knock. With normal mixtures the explosion time diminishes with increase in initial temperature and increases with increase in charge-density. The addition of about 6 per cent. of exhaust gas to a normal air-hexane mixture has but little effect in suppressing knock at 230° C. initial temperature. Comparatively large percentages of water vapour can, apparently, be added to the charge without affecting appreciably the efficiency of the conversion of the chemical energy of the fuel into pressure energy, even when the explosion time is largely affected by these additions. The results connecting tendency to knock and the richness of the charge appear to contradict experience with actual engines. The report is fully illustrated.

The Carnegie Trust for the Universities of Scotland.

EVEN a cursory perusal of the twenty-fourth annual report of the Executive Committee of the Carnegie Trust leads to the conclusion that the beneficial influence exercised by the Trustees for nearly quarter of a century in furthering the cultivation of science in the Scottish universities shows no sign of abatement. Moreover, the financial support afforded by the Trust is not confined to the universities, but is now extended to a number of colleges and institutions which are more or less closely associated with the universities and are doing work of equivalent standard. About one-half of the income of the Trust is utilised partly in the endowment of research in all branches of science and partly in assisting the universities and other institutions to provide buildings and equipment for libraries and scientific laboratories, to endow professorships and lectureships, and to develop the social side of student life by the erection of unions and hostels.

As regards the first object, a sum of more than 18,000*l*. was expended in the academic year 1924–25 in the provision of teaching fellowships, the holders of which are expected to devote most of their time to research, research fellowships and scholarships, and research grants to members of the staffs and other investigators. Grants were also made to the Scottish Marine Biological Station at Millport, the Rowett Research Institute at Aberdeen, and the Animal Breeding Research Department at Edinburgh.

For the academic year 1925–26, 20 teaching fellows, 10 research fellows, and 31 research scholars have been appointed, while in addition, grants in aid of research have been given to 36 individuals. During the year 1924–25, 17 scientific papers were published by teaching fellows, 28 by research fellows and scholars, 27 by recipients of research grants, and 13 by investigators working in the laboratory of the Royal College of Physicians; in these papers the following subjects are represented: Mathematics, physics, chemistry, geology, botany, zoology, anatomy, palæontology, physiology, pathology, medicine. The judgments of the experts appointed by the Trust to report on the work of fellows and scholars are uniformly favourable, and it is recorded that many of those who in former years were thus assisted to pursue their scientific careers now occupy prominent positions in the academic or industrial world.

With respect to the provision of opportunities for the prosecution of scientific research in the Scottish universities, the operations of the Carnegie Trust have brought about a marked change for the better. Previous to Mr. Carnegie's munificent donation, there were very few post-graduate science scholarships, and many of the most promising students were compelled, by the necessity to earn a livelihood, to leave the universities as soon as they had graduated. Now a selected number of graduates are enabled to enter upon courses of research, vastly to their own advantage and to that of the universities. Moreover, as is evidenced by the following quotation from the report, the activities of the Trust have also benefited the universities in a less direct manner: ". . . it is evident that the cause of University education commands to-day the consistent confidence and support of private benefactors and of public bodies. On more than one occasion the Committee, in intimating their quinquennial grants, have expressed the hope that these would act as an incentive in stimulating local effort to supplement the Trust's contributions, and hasten the completion of many important purposes to which the Trust were able to give only partial assistance. It is gratifying to find that a large measure of help has been forthcoming. During the past Quinquennium alone private benefactions to the four Universities have exceeded 800,000*l*. Yet large as are the sums now devoted to University work in Scotland, there are few sections which do not call for some further advance, and the help which the Trust has been able to give is to be regarded as only an indication of the opportunities which still exist to benefit the people of Scotland through the Universities."

The Genetics of Cereals.

THE study of the cytology of cereals has come to have an important place in agricultural plant breeding. In both wheat and oats, diploid, tetraploid and hexaploid species are known, the haploid number of chromosomes being seven. In rye and barley the fundamental number is the same, but polyploid varieties have so far not been discovered. But as much less work has been done with the latter cereals, it is not improbable that polyploid species may yet be found in them. Dr. K. V. Stolze[1] has published a summary of our present knowledge on this subject, in which all the earlier work is reviewed.

In certain forms of wheat and oats eight pairs of chromosomes have been described. Some of these records may be due to error, but certain of them are probably correct. Stolze suggests that such forms, which are indistinguishable from the normal, have arisen through transverse segmentation of one chromosome. This is more probable than the alternative method of origin through non-disjunction as in *Œnothera lata*, since in the latter case external differences appear. But the author himself figures in rye a homotypic nucleus with six chromosomes, which is an indication that non-disjunction occurs in this species.

The author recognises that the determination of whether, in any case, a transverse or a longitudinal split has occurred, depends largely upon comparative measurements of chromosomes and nuclear volumes. The usual view has been that in the wheats the polyploid conditions have arisen through longitudinal splitting of the chromosomes, probably accompanied by crossing. Stolze favours the view that fragmentation of the chromosomes has been concerned. Further investigations alone can settle this question. It seems very probable that both longitudinal and transverse splitting of the chromosomes have occurred in different genera of plants, but in the wheats the view of multiplication by a transverse split encounters serious difficulties, both genetical and cytological. The determination of this point would throw further light on the relationships of the various forms.

A dwarf form of wheat, which originally appeared in experiments of de Vilmorin, has since been carefully studied by Messrs. Engledow and Wadham (*Journ. Genetics*, vol. 16, No. 1), with interesting and important results. It was known that the dwarfs gave rise to talls which bred true and dwarfs which continued to 'split' in a ratio which might be interpreted as 1 : 2 : 1, including certain bushy plants which never flowered. Also, the talls and dwarfs could not always be distinguished by their heights. It was found that in each generation dense-eared plants (a safer character to deal with than dwarfness) gave (1) lax-eared, (2) dense-eared, (3) short plants with one stem and no ear, and (4) bushy pigmy plants with no ear. The last, when grown under special conditions, produced ears which were found to be denser than the normal dense-eared form. Dense-eared plants showed wide fluctuation in height, which made classification on a height basis impracticable. Usually, height and ear-density are inherited independently and are hence presumably determined by different chromosomes. It is therefore suggested that in this ever-splitting race there may have been a fusion of these two chromosome pairs, this being a part at least of the mutational change to which the dwarf form owed its origin. A number of ever-splitting races of cereals are discussed. It is hoped that a cytological investigation of this peculiar dwarf will be made, which may help to clear up the genetic peculiarities of such ever-splitting races.

---

[1] "Die Chromosomenzahlen der hauptsachlichsten Getreidearten nebst allgemeinen Betrachtungen uber Chromosomen, Chromosomenzahl und Chromosomengrosse im Pflanzenreich." Von Karl Viktor Stolze. (Bibliotheca Genetica, Band 8.) Pp. iii+71. (Leipzig: Gebruder Borntraeger, 1925.) 9.60 gold marks.

In another paper in *Journ. Genetics*, vol. 16, No. 1, Messrs. Engledow and Hutchinson give some results of crossing between *Triticum turgidum* and *T. durum* or rivet and Kubanka wheat. Since these are both tetraploid species, there is no sterility in the hybrids. The F_1 plants from this cross showed the vigour of heterozygosis. In previous experiments with wheat the endosperm characters of the seed have appeared to show maternal inheritance, in spite of the fact that double fertilisation takes place, which might be expected to lead to the phenomena of xenia, or paternal influence on the endosperm. In *T. turgidum* × *T. durum* the grains were larger than in either parent, but while intermediate in certain features, the vitreous texture and extreme hardness of the durum endosperm were dominant. Moreover, the grains on each F_1 were uniform, although the endosperm really belongs to an F_2 generation and might be expected to show recombinations. In the F_2 plants the same condition held, but in addition to the plants with endosperm like *turgidum* or like *durum*, there were other plants in which the grain showed various mixtures of the two kinds of tissue. The striking difference between the phenomena of xenia in maize endosperm and maternal inheritance in wheat endosperm leads to the suggestion that since in wheat seeds the endosperm cells are already dead, the paternal character determined by the male nuclei has not had a chance to express itself. But the same conditions would appear to obtain in the maize seed, where xenia occurs.

In these crosses the inheritance of solidness of straw has also been studied. The "lodging" of cereals is believed to be due to lack of elasticity, rather than lack of strength, in the stems. Solid straw has greater elasticity. In different varieties of wheat various kinds of solidness were found, and these were in general unifactorial differences; but the results were influenced by other factors for size of straw.

From these crosses it should be possible to produce a rivet wheat with high yield, hard, 'baking' endosperm, and solid, non-lodging straw.

R. RUGGLES GATES.

Dielectric Constant and Molecular Structure.[1]

THE physical methods for investigating the structure of molecules are principally five in number: (1) the ratio of the gaseous specific heats at constant pressure and constant volume; (2) the arrangement of atoms in crystals found by X-ray diffraction methods; (3) the molecular band spectra as interpreted by the quantum theory; (4) phenomena indicating strong fields of force around certain types of molecules; (5) refractivity and dielectric properties. The connexion between dielectric constant and molecular structure was to some extent realised by Faraday, but the theory has been developed by Lorentz, Debye, J. J. Thomson, Gans and Pauli. Recent tests have confirmed the basis of the theory.

The electrons in a molecule are displaced in an electric field, causing the appearance of an electric moment. Account must also be taken of the facts that not all electrons are similarly situated in the molecule and that an effect is produced on the field of its neighbours by the displacement of an electron. The effect produced on the displacement of any electron by that of other electrons in the same molecule must also be considered. If each molecule is a permanent electric doublet of moment μ, there is a tendency of molecules to orient themselves with their electric axes in the direction of the field. This is hindered by the thermal agitation and a statistical average degree of alignment results, depending on the moment of the doublet, the strength of the field and the temperature. All these factors are included in the equation of Debye:

$$\frac{\epsilon - 1}{\epsilon + 2} = 4\pi N\left(\frac{e^2}{3}\sum_{1}^{n} \nu_p r_p L_p + \frac{\mu^2}{9kT}\right) = \left(A + \frac{B}{T}\right)D.$$

In this ϵ is the dielectric constant; N the number of molecules per unit volume; e the electronic charge; ν_p the number of electrons of type p in the molecule; r the binding constant; L_p a factor to take account of the effect produced on the displacement of any electron by that of other electrons in the same molecule; k Boltzmann's gas constant; T the absolute temperature; A, B are constants, and D is the density.

In the case of gases the equation has only recently been tested with sufficient accuracy; ϵ is very near unity. One of the experimental methods, used by Herweg and improved by Zahn, consists in amplifying the electrical beats between two differently tuned oscillating circuits, one of which contains the experimental condenser alternately filled and emptied of gas. The electrical beats are made audible by a telephone receiver and produce acoustical beats with the sound from an electrically driven tuning-fork. This method is capable of measuring a change in capacity of one part in two millions. By plotting $(\epsilon - 1)vT$, where v is $1/D$, a straight line is obtained, from which A, the binding constant r and B, or the permanent electric moment μ of the molecule, may be computed. The values of μ so found vary from $1{\cdot}03 \times 10^{-18}$ for hydrogen chloride to $0{\cdot}06 \times 10^{-18}$ for carbon dioxide. In the case of liquids, the values vary from $0{\cdot}20 \times 10^{-18}$ for benzene to $2{\cdot}15 \times 10^{-18}$ for amyl alcohol; the value for water is $1{\cdot}98 \times 10^{-18}$. The application to liquids is not very good, probably on account of the mutual actions between molecules not allowed for in Debye's formula, and Gans has derived a much more complicated formula. C. P. Smyth has shown that it may be combined with the Lorentz dispersion formula to permit at least an *approximate* calculation of the electric moment in many cases. In some cases the moment varies with temperature, apparently due to association.

---

[1] Abstract of an address by Prof. K. T. Compton, of Princeton University, retiring vice-president of Section B (Physics) of the American Association for the Advancement of Science, delivered at the Kansas City meeting on December 30, 1925.

If assumptions are made as to the structure of molecular models, the consideration of dielectric constants will enable these to be tested, although of course it will not explicitly give us the structure of the molecule Prof. Compton gives examples of the Lewis-Langmuir type and shows that the electric moments produced by the shifts of the electrons in the formation of molecules are reasonable values.

The binding constant may also be calculated from refractivity data, and the figures derived by Born and Heisenberg, Fajans and Jooz, Smyth and others indicate that the electrons are most easily shifted in ions with small central positive charges (cores) and also in large atoms, where they are far removed from the centre. The deformability of molecules thus indicated has an important bearing on the theory of spectra, and a difficulty in the Ritz formula may perhaps be resolved if it is assumed that the electron shell is distorted by the field of the valency electron rotating about the core of the atom. Prof. Compton indicated that numerous interesting problems still await investigation in other aspects of dielectric constants.

University and Educational Intelligence.

ABERDEEN.—The Senatus has resolved to confer the honorary degree of LL.D. on Prof. F. W. Oliver, professor of botany in University College, London; Dr. R. W. Reid, emeritus professor of anatomy in the University of Aberdeen; Prof. T. B Wood, professor of agriculture in the University of Cambridge.

BIRMINGHAM.—The report of the Principal (Mr. C. Grant Robertson) presented to the annual meeting of the Court of Governors on February 25, shows that the number of students, which had been steadily diminishing since the abnormal period of inflation following the War, last year reached its minimum, and there are indications that recovery has already begun. The percentage of unmatriculated and part-time students continues to decrease.

The construction of the new block for the biological departments at Edgbaston is rapidly progressing, and it is expected that the building will be in use next session. The transfer of these departments, however, will raise a serious problem, in that the Harding Library in its present form will be quite inadequate to meet the consequent increase in the demands on its space.

The new building for the Department of Petroleum Mining is already occupied, and is shortly to be formally opened. In addition, a new laboratory has been erected for the Mining Department and equipped with large-scale experimental plant for the study of scientific and technical problems of coal treatment, the funds being provided by the Central Committee of the Miners' Welfare Fund. The Principal directs attention to the fact that the Mining Department now serves as the post-graduate mining school for the Universities of Oxford and Cambridge.

An appeal is made for more generous support of the University by the midland area generally. In particular, "What is needed to-day is the establishment, on an adequate scale, of post-graduate scholarships. Its absence is a cause of national waste; and no better service to the cause of true education and a heightened national efficiency could be rendered than by the creation of such an endowment."

CAMBRIDGE.—Mr. G. F. Shove, University lecturer in economics, has been elected to a fellowship at King's College. Mr. I. A. Richards and Mr. F. McD. C. Turner have been elected to fellowships at Magdalene College.

A slight change has been introduced into the regulations governing medical studies; it is now laid down that no student may attend any course of instruction for the third M.B. examination until he shall have passed the last part of the second examination (pharmacology and general pathology). Some 'young men in a hurry' may find this distasteful, but there is little doubt that the principle on which the change is founded is sound.

The Board of Research Studies is proposing that a summary of each successful thesis for a research degree shall be published in the *Reporter*. Such summaries would then be distributed to the universities from which non-graduate research students are drawn. The present practice is that dissertations are placed in the University Library; some of them never appear in print, and in this way good work is sometimes lost to sight and memory. It is thought that the present proposal would both obviate this possibility and also avoid overlapping in research work. Incidentally, the great increase in numbers of research students at Cambridge in recent years will become apparent.

The governing body of Emmanuel College is offering to a research student, commencing residence in October 1926, a studentship of the annual value of 150*l*. Preference will be given to a candidate who has already completed at least one but not more than two years of research. Applications should reach the Master of Emmanuel (The Master's Lodge, Emmanuel College, Cambridge, England) not later than June 30. Candidates should submit two certificates of good character, a statement of the proposed course of research, and evidence of general ability and of special fitness for the proposed course of research.

LONDON.—The offer of the Petrie Medal Committee, on behalf of the subscribers, of a Petrie Medal and Fund amounting to 75*l*. has been accepted. The Medal is to be awarded once in every three years for distinguished work in archæology, preferably to a British subject.

Prof. C. A. Lovatt Evans has been appointed as from Aug. 1 to the Jodrell chair of physiology tenable at University College. Since March 1922 Prof. Lovatt Evans has been University professor of physiology at St. Bartholomew's Hospital Medical College. During this period he has published "Recent Advances in Physiology" (1925) and edited a new edition of Bainbridge and Menzies' "Essentials of Physiology" (1925).

Dr. G. V. Anrep has been appointed as from March 1, 1926, to the University readership in physiology tenable at University College. Dr. Anrep was educated at the University of Dorpat and at the Medical Faculty of the University of Leningrad. From 1912–14 he was engaged in research work at the University of Leningrad and at University College, London. From 1917 until 1920 he was senior assistant in physiology at the Institute of Experimental Medicine of Leningrad and in 1920 he was appointed assistant, and in 1923 senior assistant in physiology at University College, London. He obtained the D.Sc. degree in physiology in 1923 and has been awarded the Schafer Prize and the Julius Mickle Fellowship (1924–25) for his research work in this University. His published work includes numerous articles in the *Journ. of Physiol.* (1912–25); *Proc. Roy. Soc.* (1923–25); and in *Heart*.

APPLICATIONS for the Beit fellowships for scientific research should be made upon a prescribed form and sent to reach the Rector, Imperial College of Science and Technology, South Kensington, S.W.7, by, at latest, April 19.

Contemporary Birthdays.

March 8, 1855. Prof. Karl E. Ritter von Goebel
March 8, 1859. Sir Robert Blair.
March 9, 1862. Sir Sidney F. Harmer, K.B.E., F.R.S.
March 10, 1858. Maj.-Gen. Sir R. Havelock Charles, G.C.V.O.
March 10, 1861. Sir Arthur E. Shipley, G.B.E., F.R.S.

Prof. KARL E. RITTER VON GOEBEL, LL.D. (St. Andrews), a foreign member of the Linnean Society, was born at Billigheim, Baden. He was educated at the universities of Tübingen, Wurzburg, and Strasbourg. Elected to the chair of botany at Strasbourg in 1881, he later occupied posts at Rostock and Marburg, down to the time when he became professor of botany at the University and director of the Royal Botanic Gardens, Munich. An authority on the mosses and liverworts (Bryophyta), some of his work has appeared in English under the titles, "Sketches of Plant Biology" (1889), "The Organography of Plants" (Oxford, 1905).

Sir ROBERT BLAIR, Education Officer of the London County Council from 1904–24, is a graduate of the University of Edinburgh. Early he had practical experience as a schoolmaster, afterwards engaging in new avenues of work as Chief Inspector, Technical Education, Ireland, 1901–4. In 1903 he was a member of the Mosely Education Commission to America. He was president of the Educational Science Section at the British Association meeting in 1920. Sir Robert has written informing papers on features of American education; on the relation of science to industry, and cognate subjects.

Sir SIDNEY HARMER, Director of the Natural History Departments, British Museum, was born at Norwich. Educated at University College, London, he graduated at King's College, Cambridge; afterwards he was Assistant Tutor there (1890–1908) and Superintendent of the University Museum of Zoology.

Sir HAVELOCK CHARLES, sergeant-surgeon to the King, is a Knight of Grace of the Order of St. John of Jerusalem. He was educated at Queen's College, Cork, Dublin, and at one or more foreign universities. He passed into the Indian Medical Service from Netley in 1882. Formerly professor of surgical and descriptive anatomy in the medical colleges at Lahore and Calcutta, he was also surgeon of the Mayo Hospital, Lahore. Sir Charles accompanied their Majesties the King and Queen to India, 1911–12. Formerly he was president of the Medical Board and Medical Adviser to the Secretary of State for India. An authority in tropical diseases, he was for some time Dean of the London School of Tropical Medicine.

Sir ARTHUR SHIPLEY, eminent as a zoologist, Master of Christ's College, Cambridge, since 1910, was educated at University College, London, and Christ's College. He was demonstrator of comparative anatomy in his university, 1885–94. From 1917–19 he was vice-chancellor of the University of Cambridge. In 1887 he was delegated by the Colonial Office to investigate a plant disease in the Bermudas. Translator of Weismann's work on heredity, he has been a voluminous writer in all branches of zoological science. Sir Arthur is chairman of council of the Marine Biological Association.

Societies and Academies.

LONDON.

Royal Society, February 25.—**O. R. Baldwin** and **G. B. Jeffery**: (1) The relativity theory of plane waves. Weyl showed that gravitational waves of small amplitude may be resolved into waves of three types—longitudinal-longitudinal (L-L), longitudinal-transverse (L-T), and transverse-transverse (T-T). Eddington showed that the only physically real waves are T-T waves, and identified a particular type of T-T wave, accompanied by an electromagnetic wave, with light. It appears that these waves are not purely periodic, but are accompanied by a cumulative change, which seems to indicate that plane light waves cannot be propagated indefinitely. Waves of *finite* amplitude are now discussed without approximation. Whether accompanied by electro-magnetic waves or not, L-L and L-T waves are fictitious, while T-T waves propagated with the velocity of light are physically real. The exact differential equation of light waves is obtained. Eddington's conclusion that plane light waves cannot be propagated without a cumulative change is confirmed by the more exact treatment. (2) Electronic orbits on the relativity theory. For an electron and nucleus attracting according to the law of the inverse square of the distance, either one can describe about the other a circular orbit of any radius, or, if on the balance there is a mutual repulsion, no circular orbits are possible. On the relativity theory the inverse square law is no longer accurately obeyed, and the circumstances in which a circular orbit can be described are less simple.—**Margaret Stimson** and **G. B. Jeffery**: The motion of two spheres in a viscous fluid. The stream function of the motion generated by two spheres moving with equal velocities in their line of centres is calculated. The fluid thrust on each of the spheres is calculated and numerical values are computed for the case of equal spheres.—**A. L. McAulay** and **F. P. Bowden**: Evidence for a film theory of hydrogen overpotential from surface tension measurements. In order that hydrogen may be liberated at the cathode a film of high surface tension must first be formed over the mercury. In a pure acid electrolyte the passage of extremely small quantities of electricity produces this film, which remains intact when the circuit passing the current is broken. Addition of small quantities of ions of metals more noble than copper destroys the film completely and instantly; metals less noble than copper leave the film intact. The film when fully formed seems to have a definite place in the electrochemical series. Production of overpotential at the cathode requires the initial establishment of the film. In building up the film, single electrode potential measured above reversible potential of mercury is proportional to surface tension of film; and finally, further addition to the film increases single electrode potential, but leaves surface tension approximately constant.—**J. H. Wolfenden**: Critical potentials of hydrogen in the presence of catalytic nickel and copper. By comparison with results obtained when molecular hydrogen was the preponderating source of ionisation, it is concluded that substantial quantities of atomic hydrogen are present at the metal surface. Similarity exists between the effect upon the form of the ionisation curve of the presence of the catalyst metal and that of an incandescent grid (as determined by Olmstead).—**J. P. McHutchison**: Adsorption experiments with radium D and radium E. An isotopic precipitate, formed under such conditions that one of the two analogous radio-active compounds is soluble, exhibits a preference for its own isotope, whereas a non-isotopic precipitate displays no such preference. The addition of a soluble lead salt to a solution of radium D and radium E stops the adsorption of radium D by charcoal, and in this way radium E has been extracted in a state of great purity. The half-life period of radium E has been so determined as 4·9 days.—**J. S. Dunn**: (1) High-temperature oxidation of metals. The oxidation of three copper-zinc alloys has been investigated. It is controlled by diffusion through a protective film of oxide, and the rate of oxidation varies exponentially with the temperature. The variation of diffusion rate with temperature is deduced. (2) The low-temperature oxidation of copper. Oxidation of copper in its normal commercial state follows the theoretical parabolic law over comparatively short time intervals. Oxidation of catalytically active copper proceeds more rapidly. The origin of this departure from the ideal law is traced to changes occurring in the oxide film, and a general parallel is established between catalytic behaviour and oxidation rate.—**J. Heyrovský**: A note on the significance of the electrode potential. The stages of the author's cycle, described by J. A. V. Butler as irreversible, involve the correct free energy terms.

Geological Society, February 3.—**S. James Shand**: The alkaline rocks and ring-intrusions of Pilansberg (Transvaal). Pilansberg, a group of hills in the western Transvaal, is the largest of the secondary eruptive complexes which are super-imposed upon the great complex of the Bushveld. The energy which caused the extrusion of the Bushveld felsites, and the intrusion of the sheets of norite and red granite, was not quite exhausted by these tremendous events; but reactions went on underground, which led to the opening of new channels through which alkaline magma ascended. Plugs and dykes of syenite and foyaite cut the granite and the norite in Sekukuniland, in the Pretoria district, and in the west, where Pilansberg presents one of the greatest intrusions of purely alkaline rocks in the world. The Berg is circular in outline, and covers about 200 square miles. The rocks may be grouped into (1) a volcanic series and (2) an intrusive series. The former includes felsites, phonolites, tinguaite, and a great development of tuff and breccia; these rocks formed a cover under which the intrusive series crystallised.

Linnean Society, February 4.—**A. Bruce Jackson**. On a new hybrid conifer (*Cupressus macrocarpa* × *nootkatensis*). The tree was raised in 1911 from seeds of a cone taken from a tree of *Cupressus macrocarpa*, growing about 50 yards from one of *C. nootkatensis*, which was evidently the pollinating plant.—**B. O. Coventry**: Coloured photographs of Cashmir plants. —**C. C. Hurst**: On the nature and origin of species in Rosa. The genus Rosa may be divided into two major groups: (1) Diploid, with 7 gametic chromosomes; (2) Polyploid, with multiples of 7. Diploids fall naturally into 5 discontinuous species which breed true to their structural characters, are intrafertile and intersterile. Polyploids (except a few duplicated cultivated forms) are composed of various combinations of characters and chromosomes of the 5 diploid species. Chromosomes of diploid and polyploid species may be frequently observed working in septets during mitosis and meiosis. This presents a new mode of heredity with non-Mendelian ratios, and offers a solution of the problem of the inheritance of acquired characters. Three diploid species which do not conform to the septet formulæ are classed as distinct genera; they may be relics of the Tertiary flora. The distribution of species coincides with accepted views of the arctic origin of the land flora of the northern hemisphere, and points to an origin by descent from an arctic decaploid species with 5 double septets of chromosomes and characters, generalised and adapted to variable conditions, which, by successive losses of whole septets, gave rise to the lower polyploid species and eventually to the five specialised diploid species. The original decaploid species would most probably arise by duplications of an ancient diploid species under luxuriant conditions. This would be followed, in secular time, by differentiation of the five double septets of chromosomes and characters by duplicational segregations and gene mutations. Evolution would be an alternating process, from diploid to polyploid species (*i.e.* creative) and from polyploid to diploid species (*i.e.* emergent), according to geological conditions.

Optical Society, February 11.—**W. M. Hampton**: The annealing and reannealing of glass. (iii.) The determination of annealing temperatures. The formulæ deduced in pts. i. and ii. are applied to the case of heating glass under constant gradient, and the temperature at which strain disappears is obtained, the effect of the known change in the coefficient of expansion on this temperature being discussed. (iv.) The annealing of glass at low temperatures. The annealing equation is considered from the point of view of dimensions.—**F. W. Preston**: The nature of the polishing operation. The evidence for the existence of a surface layer on polished glass differing from the underlying material and from the surface layers of ground, or fire-glazed glass, or crystalline surface layers in the case of quartz, is slight or negative. The polishing process may be one of ultramicroscopic abrasion complicated by the fact that the fissures produced by one grain of the abrasive lie in the territory of its neighbour, and that the abrading efforts of the several grains tend to neutralise one another.

DUBLIN.

Royal Irish Academy, January 25.—**H. Ryan** and **Amy Markey**: The action of nitric acid and of nitrogen peroxide on triphenylamine. Nitrogen peroxide converted triphenylamine (in solution) into a tetranitrotriphenylamine which did not melt below 280° C. Nitric acid at the ordinary temperature and at low concentrations in acetic acid or carbon tetrachloride solution converted triphenylamine into the same tetranitro derivative, and in addition to it a trinitro derivative melting at 219° C. and a hexanitro derivative melting at 272° C. were obtained. The nitrotriphenylamine melting at 139° C. previously obtained by Herz (*Ber. Chem. Ges.*, 18, p. 2157) was shown to be 4-nitrotriphenylamine by synthesis from 4-nitrodiphenylamine.—**H. Ryan** and **Mary Glynn**: The relative speeds of the removal of nitric acid from systems containing certain aromatic compounds. Equimolecular amounts of nitric acid and diphenylamine, diphenylnitrosamine, stilbene, phenylbenzyl ether, diphenyl ether, o-tolylurethane, diphenylurethane, and ethyl-o-tolylurethane respectively were allowed to interact at the same concentrations in carbon tetrachloride solution at 60° C. The speed of the removal of the nitric acid was greatest in the case of diphenylamine and diphenylnitrosamine. The initial speed in the case of stilbene was greater than that with phenylbenzyl ether. Diphenyl ether reacted less rapidly than phenylbenzyl ether but more rapidly than the urethanes.—**H. Ryan**, **D. T. Flood**, and **P. T. McNulty**: The nitric compounds of β-dinaphthylene oxide. β-dinaphthylene oxide, in carbon tetrachloride solution and at the ordinary temperature, was converted by nitric acid at low concentrations into mononitro-β-dinaphthylene oxide, melting at 185° C., which was previously obtained by Hodgkinson and Limpach (*J.C.S.*, 59, p. 1100), and a dinitro-β-dinaphthylene oxide melting at 318° C. The latter substance was also got by the action of nitrogen peroxide on β-dinaphthylene oxide in acetic acid solution, but in the absence of a solvent a tetranitro-β-dinaphthylene oxide decomposing about 320° C. was obtained. Another crystalline tetranitro-β-dinaphthylene oxide melting with decomposition at 342° C. was formed by treating the dinaphthylene oxide with fuming nitric acid

EDINBURGH.

Royal Society, February 8.—Henry **Briggs**: The Wheatstone bridge as the means of measuring linear and angular dimensions at a distance, and its application to borehole surveying. The paper consisted for the most part of a description of the author's borehole surveying instrument known as the "Clinophone." In this instrument, by means of liquid resistances held in shallow cups provided with electrodes, the principle of Wheatstone's bridge can be utilised in obtaining polar co-ordinates and in reading such co-ordinates at any distance. Thus a transmitter, placed in a borehole of any depth, automatically furnishes messages to a surface receiving station, from which the direction and amount of deviation from the perpendicular of the hole can be obtained.—E. T. **Whittaker**. On the adjustment of Sir J. J. Thomson's theory of light to the classical electromagnetic theory. In a recent paper Sir J. J. Thomson has suggested a corpuscular or quantum theory of light, in which the light is supposed to consist of closed circular tubes of electric force moving, with the velocity of light, at right angles to their planes, like vortex-rings. This theory is now brought within the compass of the classical Maxwell-Lorentz theory of the electromagnetic field. Thomson's theory is extended by adjoining to the Maxwell-Lorentz equations certain terms which represent a "magnetic current." Any theory of the type of Thomson's necessarily involves the introduction of these terms. A kind of "electric vortex-ring" is thus obtained and expressed analytically: such a structure would behave as a light quantum.

LEEDS.

Philosophical and Literary Society, January 27.—W. P. **Milne**: The ten nodes of the Hessian of the cubic surface.—S. **Brodetsky**: The equations of the gravitational field in orthogonal co-ordinates. The equations of the gravitational field in Einstein's theory, when put down in their general form in terms of tensors, have the disadvantage of not being immediately intelligible. On the other hand, if an attempt is made to write out the equations in explicit form, the result is too complicated for analytical use. The gravitational equations are now worked out in terms of orthogonal co-ordinates with no other restriction. The similarity with Lame's transformation of Laplace's equation is interesting and suggestive.—E. C. **Stoner**: The atomic moments of ferromagnetics. The magnetic moment per atom of ferromagnetic metals and alloys may be found from the variation in susceptibility with temperature above the Curie point, and from the saturation intensity of magnetisation at low temperatures. Interpreted on the basis of the quantum theory of atomic magnetism, the apparently discordant values deduced by the two methods are compatible with each other, and with the values found for paramagnetic ions in solid salts and solutions.—G. F. **Brett** and R. **Whiddington**: Note on the passage of electrons through small apertures. It has been found in agreement with previous workers that if electrons *in vacuo* are accelerated towards an anode furnished with a narrow and more or less central aperture, only a small fraction of those electrons which appear on the further side have energies corresponding to the full potential difference. When the magnetic spectrum is examined, there is not a continuous gradation of energies as hitherto supposed, but a many-lined or banded spectrum depending on the conditions of the experiment.—H. S. **Patterson** and B. **Whytlaw-Gray**: Photophoresis. Photophoresis is of very general occurrence; it varies from substance to substance, and the negative effect never occurs without the positive. In some substances the negative effect is very difficult to detect. The effect is most marked with highly absorbent bodies such as carbon and organic dyestuffs.—Mrs. M. S. **Burr**: Preliminary note on solvate formation. An equation has been deduced representing the solubility of 2 : 4-di-nitrotoluene in sulphuric acid-water mixtures of different concentrations between 84·5 per cent. and 95 per cent. acid. Similar equations appear to be valid for other nitro-compounds, and may be explained by supposing that the solute forms, with the better solvent, a continuous series of solvates in equilibrium with a certain amount of free solute. The application of the equation may be complicated by the formation of compounds between the two constituents of the solvent, although no great difficulty is experienced where the compound is sharply defined, as, for example, in sulphuric acid monohydrate.—Sylvia **Garstang** and W. **Garstang**: Preliminary note on the development of Botrylloides and its bearing on the ancestry of the Chordata. The inclusion (Tunicata) or exclusion (Amphioxus-Craniata) of the hypophysial region within the neural folds is compared with the continuity or discontinuity of the longitudinal ciliated bands of echinoderm larvæ. The evolution of Chordata is due to elaboration of the original larval organisation, and its partial (Tunicata) or complete (Amphioxus-Craniata) supersession of an original sessile adult condition (*i.e.* pædomorphosis).—D. **Greenwood** and W. H. **Pearsall**: Observations on geotropism. Earlier conclusions are confirmed that geotropic curvatures are associated with changes in the hydrogen-ion concentration of tissues during the period of curvature. In *Vicia faba* stems and roots, the convex flank is slightly more acid. The differences in *p*H value observed are sufficient to cause differences in volume on the convex and concave flanks and hence to account for the curvatures observed. The different behaviour of the stem and root is associated with observations on the *p*H value of the fluids exuded from stem and root—these being of low *p*H in the stem. It is also found that geotropic curvature is more rapid in plants grown in the light (as compared with those kept in the dark), and also in plants which have been exposed to coal-gas.

PARIS.

Academy of Sciences, January 25.—Léon **Guillet**: The properties of certain treated chrome-nickel steels. It is known that under certain conditions of heat treatment, some special steels, especially chrome-nickel steels, become very fragile, although their other mechanical properties remain practically unchanged. Details are given of experiments forming a systematic study of this phenomenon.—A. **Vayssière**: The systematic position of the genus Erato, a prosobranch gasteropod mollusc.—A. **Myller**: The wrapping of surfaces.—Arnaud **Denjoy**: The iteration of analytical functions —D. **Mordoukhay-Boltovskoy** . The generalisation of the theorem of Eisenstein indicated by Tchebychef.—René **Lagrange** : A class of conformal representations.— — **Kivélioviteh** : The calculation of the conditions of primary shock in the problem of three bodies.—V. **Fock** : The reduction of the plane problem of elasticity to an integral equation of Fredholm.—Bernard **Lyot** : The polarisation of the planet Venus. The explanation of the polarisations found for Venus would appear to depend on the properties of clouds formed of minute drops of water.—E **Darmois** and P. **Gabiano** : The polarimetric study of mineral and organic dimolybdomalates. An application of Oudemans' law. An extension of work already published on the dimolybdomalates of sodium and ammonium to other bases (lithium, potassium, aniline, barium, calcium, methylamine, etc). All these are characterised by the anion $4MoO_3,2C_4H_4O_5$ —V. **Posejpal** : Resonance absorption in the domain of the X-rays.—Jean **Gandillot** : The presence of a bed of coal in the metamorphic strata to the south of Limoges.—P. **Fallot** and R **Bataller** : The tectonic of the mountains between Montalban and the coast of the Province of Castellon (Spain).—L **Eblé** and J **Itié** : The values of the magnetic elements of the station of Val-Joyeux (Seine-et-Oise) on January 1, 1926.—L. **Blaringhem** : Methods and results in the formation of hybrids of flax.—Mlle. Laura **Kaufman** . The growth of the body and organs of the pigeon.—Lucien **Daniel** : The variations of inulin in the grafted Jerusalem artichoke.—F. **Granel** : The morphological and functional signification of the pseudobranchia of fishes.—Auguste **Lumière** : The invisibility of certain flocculates —Mme. **Phisalix** · The rabicidal power of the blood of the hedgehog.—H **Violle** . The antiseptic power of chloropicrin. Details of experiments proving the great antiseptic power of aqueous solutions of chloropicrin with various types of pathogenic organisms.

February 1.—H. **Deslandres** : The magnetic perturbation of January 26, 1926, at the Meudon Observatory. This magnetic storm was indicated on the recording instruments for about 15 hours, and at the same time an aurora borealis was visible. The state of the sky prevented simultaneous observations of the sunspots with the spectro-heliograph. Measurements of the intensity of wireless waves received from Rome and Bordeaux are made daily at the Observatory, and on this day it was noticed that the intensity of reception was greatly increased, those from Rome being about four times the average strength.—A. **Blondel** : The reversibility of frequency multipliers with iron cores.—V. **Grignard** and F **Chambret** · The ketonic splitting of the tertiary alcohols. The decomposition by distillation of tertiary alcohols into water and an unsaturated hydrocarbon is well known, but in a few cases a splitting into ketone and hydrocarbon has been observed. It has been found that under certain conditions, detailed in the paper, the dehydration can be suppressed and the formation of ketone increased.—M. Camille Matignon was elected a member of the section of Chemistry in succession to the late M. A. Haller.—Charles **Jordan** : New developments for the application of the theorem of Bernoulli —N. **Mandelbrojt** : Transcendant numbers and analytical functions.—Nikola **Obrechkoff** : The summation of divergent series and the analytical prolongation.—V **Nechville** : A new form of differential equations of the restricted elliptic problem.—Jean **Fallou** and A. **Mauduit** : The maintenance of a non-sinusoidal free oscillation by resonance of one of its harmonics.—Pierre **Thomas** and Mlle. Marie **Sibi** : Contribution to the study of the structure of jellies Details of the study of the behaviour of the gel formed by the dibenzoyl acetal of sorbite.—Etienne **Audibert** : The mechanism of the fusion of coal. A study of the effect of rate of heating on coke formation.—Louis **Grenet** : Quasi-limiting states in crystallised bodies —Ch. **Courtot** and Jan **Krolikowski** : A new preparation of α-indanone. This substance is obtained with yields of 90 to 95 per cent. by the oxidation of α-chlorindane with chromic acid. Crude indene, obtained by a careful rectification of phenolic oils from coal tar and subsequent removal of phenols by soda, can be converted into the chlorindane by hydrochloric acid.—**Pastureau** and Mlle. **Zamenhof** . The preparation of propylidene and isoamylidene acetone with intermediate production of the corresponding ketols. Propionic aldehyde and alcohol are condensed with aqueous soda in the presence of ether to the ketol $CH_3-CH_2-CH(OH)-CH_2-CO-CH_3$ and this is readily dehydrated by oxalic acid to the unsaturated ketone. Isoamylidene acetone is obtained by a similar reaction.—L **Royer** : The mutual orientations of crystals determined by the single coincidence of a plane link of the two species.—Ch. **Maurain** and L. **Eblé** : The magnetic storm of January 26, 1926. Details from the records of the magnetograph at the Val-Joyeux Observatory —Raymond **Chevallier** : Extinction of the magnetic perturbations at the periphery of Etna.—Jean **Dufay** Polarisation of the light from the nocturnal sky.—P. **Lavialle** : The polymorphism of the anthers in *Knautia arvensis* —Pierre **Lesage** : The carnosity of the cotyledons and the bushy form of the stem in *Lepidium sativum* acclimatised to salt water.—Francois **Pellegrin** : The affinities of the flora of the volcanic summits of Tibesti (Central Africa) —R. **Souèges** : Embryogeny of the Umbelliferæ : The development of the embryo in *Carum Carvi*.—Armand **Dehorne** : Cytological indices of the presence of cholesterol in the normal eye —J. **Wolff** : The presence in various fungi of an oxydase not previously described. In a certain number of fungi there exists an oxydase, accompanying laccase and tyrosinase but distinct from these two ferments, which has the property in the presence of oxygen of oxidising ferrous salts of organic acids to ferric salts. The name ferrase is proposed for the ferment.—G. **Leven** and Emile **Coudert** : New data on the pathogeny and therapeutics of incoercible vomiting in pregnancy.—Georges **Mouriquand** : Pellagra. Its experimental realisation.—L. **Auger** : The experimental realisation of vitular fever.

MELBOURNE

Royal Society of Victoria, December 10.—E. **Kidson**: The annual variation in the velocity of cirrus clouds over Melbourne. The velocities were deduced from nephoscope observations. The predominating westerly component has a marked minimum (16·5 m/s) in February, a second in May, then rises to a maximum (26·3 m/s) in November. The variation is of a similar type for the south component, but opposite for the north and east. There is close correlation for each component between the velocity and the frequency of observation. The resultant mean direction is approximately 270° from January to April, 280° from May to August, thence veering to 265° in December.—Gerald F. **Hill** : Australian termites (Isoptera). Notes on Stolotermes, Calotermes, and Coptotermes with descriptions of new species.—New or little-known fossils in the National Museum, Pt. **xxix**.—On some tertiary plant remains from Narracan, S. Gippsland. The flora described occurs in a comparatively thin seam on the Ten Mile Creek near Thorpdale, and is part of a thick bed of sandstone and quartzite underlying the older basalt. It is apparently older than that of the Morwell Coal, and of a kind that compares closely with Berwick in Gippsland, and even with Dalton near Gunning, New South Wales. The "Acer" earlier recorded from the Australian Tertiary undoubtedly belongs to Sterculia.—**A. J. Ewart** and **A. H. K. Petrie**: Contributions to the flora of Australia (xxxi). Noteworthy among the new genera and species from the Northern Territory are the genera Wycliffea and Sideria, the former of which belongs to the Caryophyllaceæ and shows a response to xerophilous conditions by complete cleistogamy, while the latter belongs to the Malvaceæ and shows remarkable reduction of the andrœcium.—**A. D. Hardy**: Delayed dehiscence affecting several species in the families Myrtaceæ, Proteaceæ, and Coniferæ. A hedge of *Hakea leucoptera*, twenty years old, has retained its earliest fruits unopened, and several young "Cypress pines" have withheld seed of six years of fruitings. In Callistemon and Melaleuca delay is habitual. Some hedge plants of *Cupressus macrocarpa* showed five years' reservation. In *Eucalyptus platypus* var. *acuminatus* specimens from one tree in various stages showed that in six years the inch-long umbel stalks became immersed in the stem or branches. *Protea mellifera* and *Isopogon ceratophyllus* retain indehiscent fruits in persistent heads.

ROME.

Royal Academy of the Lincei, December 1925.—**G. Bruni** and **A. Ferrari**: Solid solutions between compounds of elements of different valency. Anhydrous lithium and magnesium chlorides. When examined by the powder method, anhydrous magnesium chloride gives a photogram corresponding with a cubic lattice coincident with that of lithium chloride; the elementary cell contains two molecules of magnesium chloride or four molecules of lithium chloride. Since the magnesium salt is doubly refracting and uniaxial, it has a pseudo-cubic structure belonging to one of the tetragonal or hexagonal systems.—**F. Zambonini** and **R. G. Levi**: Isomorphism of molybdates of rare earth metals with those of calcium, strontium, barium and lead. In the isomorphous molybdates of the alkaline-earth and cerium group metals, the elementary solids are found to contain equivalent volumes of these compounds.—**E. Bompiani**: Construction of projective-differential invariants of a surface.—**Carlo Severini**: Convergence of the series of orthogonal functions.—**Beniamino Segre**: Quadratic complexes of straight lines of S_4.—**Giovanni Sansone**: Indeterminate equations of the unit of negative type in real quadratic bodies.—**Antonio Signorini**: Presso-flexion of masonry.—**Arnaldo Belluigi**: Somigliana's theory of seismic waves.—**G. Natta**: Crystalline structure of cadmium and nickel hydroxides. For these hydroxides, which crystallise in the rhombohedral system, the dimension of the cell has been verified by calculation of the density and the atomic arrangement controlled by calculation of the intensity, various values being ascribed to the parameters. Both hydroxides are analogous in structure to magnesium and manganese hydroxides.—**A. Terni** and **C. Padovani**: Action of sodium hypophosphite on stannic chloride. In dilute solution these compounds do not appear to interact, but at higher concentrations they yield a voluminous white precipitate of the formula, $SnCl_4$, $Sn(H_2PO_2)_4$, $3H_2O$.—**Nathan Shalem**: A new cenomanian fauna of Palestine.—**Virginia Gennaro**: Piedmontite in mica-schists in the Lanzo valleys (Piedmont Alps).—**G. Amantea** and **G. Martino**: Investigations on spermatic secretion (xvii). Fasting and testicular activity in the pigeon.—**Luigi De Caro**: Variations of the electrical resistance of the muscles.

VIENNA.

Academy of Sciences, December 17.—**M. Kohn** and **A. Segel**: Communications on bromo-phenols, (xix.). Brominated nitro- and dinitro-cresol.—**L. Schmid** and **B. Becker**: Condensation of 2-amino pyridine with thiophosgene, and condensation of 2-amino pyridine with aliphatic aldehydes.—**E. Schrödinger**: The relation of the four-colour to the three-colour theory.—**L. Waldmann**: Geological survey of the Moravian mountain foundations north of Sigmundsherberg.—**R. Andreasch**: Carbamide and guanidine derivatives of the sulpho fatty acids (iv).—**O. Abel**: An attempted solution of the Flysch problem. The Flysch sediments in the Alps and Carpathians are very uniform, poor in fossils, with unexplained traces of life and associated with petroleum, suggesting that the Flysch must be a shallow water deposit. The mangrove swamps of south Florida and of Cuba suggest that the Inoceramen strata of the Alps and Carpathians may have been laid down in a tidal mangrove girdle.—**H. Handel-Mazzetti**: New Chinese plants (xxxviii.), with index to species described during the year 1925.—**R. Schwinner**: Mountain land north-east of Graz.

Diary of Societies.

SATURDAY, MARCH 6.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 10.30 A.M.—Sir William Milligan: Hæmorrhagic Types of Ear Disease occurring during Epidemics of Influenza.—H. G Batcourt: Gradenigo's Syndrome.—Dr. A. R. Friel: Demonstration of Experiments on Ion Action.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (1).

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—Annual Conversazione.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch) (at College of Technology, Manchester), at 4.—G. Mortimer: Aluminium Foundry Practice.

MONDAY, MARCH 8.

ROYAL SOCIETY OF EDINBURGH, at 4.30.—Miss N. B Eales: The Anatomy of the Head of a Fœtal African Elephant, *Elephas africanus* (*Loxodonta africana*).—Dr. C. M. Yonge: The Digestive Diverticula in the Lamellibranchia.—Prof. W. Peddie: Present Problems in Colour Vision: the Laws of Visual Fatigue, and of Resultant Sensation.—Dr F. A. E. Crew: Fertility in the Domestic Fowl.—Prof. H. W. Turnbull: The Invariant Theory of Forms in Six Variables relating to the Line Complex.—*Read by title only*:—Prof. P. Humbert: Some Hyperspace Harmonic Analysis Problems introducing Extensions of Mathieu's Equation.—W. Saddler: A Geometry associated with the Double Binary (2 2) Form.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. J. Barcroft: The Egg (4): The White.

INSTITUTION OF STRUCTURAL ENGINEERS (Students' Meeting) (at 2 Victoria Street), at 6.—H. J. Deane and others: Discussion.

INSTITUTION OF AUTOMOBILE ENGINEERS (Birmingham Centre) (at Chamber of Commerce, Birmingham), at 7.—Mr. Topliss: The Metallurgist in Inspection and Design.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—F. Creedy and others: Discussion on A Recent Development in A.C. Apparatus.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—R. B. Matthews: Electro-Farming; or the Application of Electricity to Agriculture.

GLASGOW UNIVERSITY ALCHEMISTS' CLUB, at 7.30.—Annual General Meeting.

INSTITUTE OF METALS (Scottish Local Section) (Annual General Meeting) (at Institution of Engineers and Shipbuilders in Scotland, 39 Elmbank Crescent, Glasgow), at 7.30.—W. R. Barclay: Nickel and its Alloys.

BRITISH PSYCHOLOGICAL SOCIETY (Education and Medical Sections) (at Royal Society of Medicine), at 8.—Drs. Cyril Burt, M. Hamblin Smith, W. Rees Thomas, F. C. Shrubsall, and A. F Tredgold: Symposium on The Definition and Diagnosis of Moral Imbecility.

SURVEYORS' INSTITUTION, at 8.—Discussion on papers by C. P. Sanger, Sir John Oakley, C. H. Bedells, F. W. Hunt, and H. E. Sherwin on The Various Statutes which comprise the New Law of Property.

MEDICAL SOCIETY OF LONDON, at 8.30.—Sir Thomas Horder, Dr. C E. Lakin, and others: Discussion on Obscure Pyrexia in Adults.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.

INSTITUTE OF CHEMISTRY (Manchester and District Section).—Dr M. Young: The Endocrine Glands.

TUESDAY, MARCH 9.

MANCHESTER GEOLOGICAL AND MINING SOCIETY, at 4.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY, at 4.—Prof. G. Elliot Smith: Brains of Apes and Men (Wilde Memorial Lecture).

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Prof. W. W. C. Topley: Experimental Epidemiology (Milroy Lectures) (3).

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—Dr. A. Wade: The Search for Oil in Australia.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. F. P. Stowell: The Purification of Sea-Water by Storage.—Dr. F. B. Nopcsa: Heredity and Evolution.—Dr. W. C. Osman Hill: A Comparative Study of the Pancreas.—Isabella Gordon: Notes on a Number of Muriceid Genera (*Alcyonaria Gorgonaceae*) with Special Reference to Spiculation.

INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—E. A. Chattock: Address.

INSTITUTION OF ELECTRICAL ENGINEERS (Scottish Centre) (at North British Station Hotel, Edinburgh), at 7.—Prof. S. P. Smith: An All-Electric House.

ROYAL PHOTOGRAPHIC SOCIETY, at 7.—Annual General Meeting.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch, Burnley Section) (at Burnley Municipal College), at 7.15.—A. E. Wilson: The Usefulness of Wood Patterns mounted on Boards.

INSTITUTION OF AUTOMOBILE ENGINEERS (Coventry Centre) (at Broadgate Café, Coventry), at 7.30.—P. Brewster: The Preparation of Motor Cycles for Speed Events.

INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 7.30.

QUEKETT MICROSCOPICAL CLUB, at 7.30.—D. J. Scourfield: A Microscopic Fossil Crustacean from the Rhynie Chert, Aberdeenshire.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, at 8.—Edmund White: British Pharmacy and its Relation to Continental Practice.

ROYAL SOCIETY OF MEDICINE (Surgery, Medicine, Electro-Therapeutics, and Therapeutics Sections), at 8.—Discussion on The Treatment of Exophthalmic Goitre (continued).

WEDNESDAY, MARCH 10.

INSTITUTE OF METALS (Annual General Meeting) (at Institution of Mechanical Engineers), at 10 A.M. and 2.—G. Mortimer: The Die-Casting of Aluminium Alloys—A Review of Current Methods.—S. L. Hoyt and T. R. Schermerhorn: The Hardness of Cold-Rolled Copper.—R. W. Bailey: Note on the Softening of Strain-Hardened Metals and its Relation to Creep.—W. Feitknecht: Crystal Growth in Recrystallised Cold-Worked Metals.—R. Genders: The Interpretation of the Macrostructure of Cast Metals.—W. L. Kent: The Brittle Ranges of Bronze.—D. Stockdale: The Copper-Rich Aluminium-Copper-Tin Alloys.

INSTITUTE OF HYGIENE, at 3.30.—Dr. C. E. Shelly: The Incidence of Infectious Diseases in Public Schools.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. J. E. Marr: The Pleistocene Deposits of the Lower Part of the Great Ouse Basin.—Sir T. W. Edgeworth David and Dr. W. G. Woolnough: Cretaceous Glaciation in Central Australia.

INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at Birmingham University), at 7.—R. B. Matthews: Electro-Farming; or the Application of Electricity to Agriculture.

INSTITUTE OF METALS (Swansea Local Section) (at University College, Swansea), at 7.15.—Discussion on Annealing.

RADIO SOCIETY OF GREAT BRITAIN (at Institution of Electrical Engineers), at 7.30.

ROYAL SOCIETY OF ARTS, at 8.—Dr. R. Thiessen: The Microstructure of Coal.

INSTITUTION OF CHEMICAL ENGINEERS (at Burlington House), at 8.—H. M. Dunkerley: Refrigeration in Chemical Manufacturing Processes.

ROYAL SOCIETY OF MEDICINE (Surgery, Medicine, Electro-Therapeutics, and Therapeutics Sections), at 8.—Discussion on The Treatment of Exophthalmic Goitre (continued).

EUGENICS EDUCATION SOCIETY (at Royal Society), at 8.30.—Dr. A. S. Parkes: Sterility and Vitamin Deficiency: a Review.

INSTITUTION OF STRUCTURAL ENGINEERS (Lancashire and Cheshire Branch).—R. Travers Morgan: Building Construction from a Surveyor's Point of View: a Survey of Regulations governing Buildings.

THURSDAY, MARCH 11.

INSTITUTE OF METALS (Extraordinary General Meeting and Adjourned General Meeting) (at Institution of Mechanical Engineers), at 10 A.M. and 2.—T. B. Crow: Some Experiments on the Soft-Soldering of Copper.—A. Glynne Lobley and D. Jepson: The Influence of Gases on Copper at High Temperatures. Part I.—A. J. Murphy: The Constitution of the Alloys of Silver and Tin.—W. Hume-Rothery: Researches on the Nature, Properties, and Conditions of Formation of Intermetallic Compounds, with Special Reference to Certain Compounds of Tin. Parts I.-V.—H. J. Tapsell and J. Bradley: The Mechanical Properties at High Temperatures of an Alloy of Nickel and Copper, with Special Reference to Creep.—B. S. Evans and H. F. Richards: Determination of Zinc Oxide in Brass.—Prof. C. O. Bannister: Note on the Corrosion of an Ancient Tin Specimen.—A. M. Portevin: Striation due to Working or to Corrosion in Microscopical Metallography. A Contribution to the Study of the Mode of Action of Etching Reagents.

ROYAL SOCIETY, at 4.30.—J. A. Campbell: The Effects of Ultra-Violet Radiation upon the Metabolism of Healthy Subjects.—E. Ponder: A Study of certain Forms of Inhibition and Acceleration of Hæmolysis.—Dr. S. B. Schryver and H. W. Buston: The Isolation of some Undescribed Products of Hydrolysis of Proteins.—*To be read in title only*: —A. W. Greenwood and Dr. F. A. E. Crew: Studies on the Relation of Gonadic Structure to Plumage Characterisation in the Domestic Fowl.—Prof. E. P. Cathcart and W. A. Burnett: The Influence of Muscle Work on Metabolism in varying Conditions of Diet.—E. Fischer: The Heat liberated by the Beating Heart.

ROYAL ANTHROPOLOGICAL INSTITUTE (Edinburgh and the Lothians Branch) (at Royal College of Surgeons, Edinburgh), at 5.—D. M. Greig: Prehistoric Trepanning.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—R. H. Fowler: Atom-Mechanics (Lecture).—W. Saddler: Apolar Triads on Cubic Curves.—J. H. Grace: (a) A Point in Enumerative Geometry; (b) The Four-square Theorem.—W. H. Baker: A Particular Cubo-cubic Cremona Transformation.—H. B. C. Darling: On the Sums of Divisors of Numbers (Moduli 3 and 6).—Prof. G. H. Hardy: A Theorem Concerning Harmonic Functions.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. B. Hart: The Development of Psycho-pathology and its Place in Medicine (Goulstonian Lectures) (1).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Dr. C. D. Ellis: The Atom of Light and the Atom of Electricity (5).

ROYAL AERONAUTICAL SOCIETY (Students' Section), at 6.—Flying-Officer R. L. Ragg: Experimental Flying from the Pilot's Point of View.

SOCIETY OF CHEMICAL INDUSTRY (Chemical Engineering Group) (jointly with the Bristol Section of the Society) (at Bristol University), at 6.—A. Ogilvie: Sifting Plant.—T. J. Stevenson: Sifting Machinery and Processes.

INSTITUTION OF ELECTRICAL ENGINEERS (Dundee Sub-Centre) (at University College, Dundee), at 7.30.—A. F. Stevenson: Cable Troubles.

OPTICAL SOCIETY (at Imperial College of Science), at 7.30.—R. Kingslake: Application of the Hartmann Test to the Measurement of Oblique Aberrations.—W. G. Collins: Some Physical and Optical Characteristics of the Stylus-on-Celluloid Method of Recording.

INSTITUTION OF ELECTRICAL ENGINEERS (Irish Centre (Dublin)) (at Trinity College, Dublin), at 7.45.—Dr. J. F. Crowley: Recent Developments in the Production of Synthetic Ammonia.

ROYAL SOCIETY OF MEDICINE (Neurology Section) (at National Hospital for the Paralysed and Epileptic, Queen Square), at 8.

FRIDAY, MARCH 12.

ROYAL ASTRONOMICAL SOCIETY, at 5.—P. ten Bruggencate: Note on the Problem of Cepheid-Variation.—S. D. Tscherny: Occultations of Stars and Planets by the Moon, observed at Kiew in the year 1925.—W. Eichelberger and A. Newton: The Orbit of Neptune's Satellite and the Pole of Neptune's Equator.—Dr. H. Spencer Jones: Note on the Secular Motion of the Pole.—Prof. R. A. Sampson: The Structure of the Solar Cluster.—M. C. Johnson: The Velocities of Ions under Radiation Pressure in a Stellar Atmosphere, and their Effect in the Ultra-Violet Continuous Spectrum.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section) (Clinical Meeting) (at Royal London Ophthalmic Hospital, City Road), at 5.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—E. M. Archer: Heat Losses from Vacuum Vessels.—Dr. A. H. Davis: A Ripple Tank for the Study of the Acoustics of Buildings.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of Parts concerned in the Secretion and Absorption of Cerebrospinal Fluid.

MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society), at 6.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (jointly with Institution of Electrical Engineers) (at Armstrong College), at 7.—R. W. Gregory: Paper.

ROYAL PHOTOGRAPHIC SOCIETY, at 7.—J. E. Hodgson: Whaling in the South (Lecture).

INSTITUTE OF METALS (Swansea Local Section) (at University College, Swansea), at 7.15.—Discussion on Annealing.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (at Swansea Technical College), at 7.30.—E. A. Tyler: Some Notes on Pure Chemicals: An Inquiry into the Purity of Available Supplies.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—F. E. Webb: Paint Spraying.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Newcastle-upon-Tyne), at 7.30.—E. J. Eyres: What is Sea Speed?

ROYAL SANITARY INSTITUTE (at Town Hall, Hastings), at 8.—Prof. H. R. Kenwood: A City of Health (Lecture).

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir J. J. Thomson: Radiation from Electric Discharges.

WEST OF SCOTLAND IRON AND STEEL INSTITUTE (at Royal Technical College, Glasgow).—J. Mitchell: Corrosion.

SATURDAY, MARCH 13.

ROYAL SANITARY INSTITUTE (at Town Hall, Hastings), at 10.30 A.M.—Dr. G. R. Bruce, Miss Hester Viney, Dr. J. Fenton, and others: Discussion on Mothercraft and Fathercraft.—J. Parkin, H. T. Taylor, and others: Discussion on The Effect of the Public Health Act of 1925 on the Work of Municipal Engineers and Sanitary Inspectors.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (2).

SCOTTISH JUNIOR GAS ASSOCIATION (at Royal Technical College, Glasgow), at 7.—S. H. Hunter: Scientific Service.

BIOCHEMICAL SOCIETY (at University College).

PUBLIC LECTURES.

SATURDAY, MARCH 6.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: The Other World of the Ancient Egyptians.

MONDAY, MARCH 8.

UNIVERSITY OF LEEDS, at 5.15.—Prof. W. H. Lang: The Flora of the Devonian Period.

TUESDAY, MARCH 9.

UNIVERSITY COLLEGE, at 5.30.—Dr. C. U. Ariens Kappers: The Evolution of the Nervous System. (Succeeding Lectures on March 10, 11, and 12.)

WEDNESDAY, MARCH 10.

LONDON SCHOOL OF ECONOMICS, at 5.—Prof. A. Radcliffe-Brown: The Study of Backward Peoples: its Method and Practical Value. (Succeeding Lectures on March 12 and 15.)

THURSDAY, MARCH 11.

ROYAL SOCIETY OF ARTS, at 8.—W. A. Harvey: Housing, Past, Present, and Future. Its Effect on the Health and Outlook of the People (Chadwick Lecture).

SATURDAY, MARCH 13.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. H. Graham Cannon: How Animals Feed and what they Eat.

SATURDAY, MARCH 13, 1926.

British Science and Invention.

Of the importance of research to the electrical industry, or of the notable improvements in machines, appliances, and processes brought about in the industry by special investigation, there can be no question. The new types of electric lamps, which give far better light at a smaller cost than those they superseded, and the new forms of submarine cables enabling speeds of working to be increased three or four times, are but two familiar instances of the happy results of successful research. Formerly progress was achieved mainly by the discoveries of inquirers working single-handed, but nowadays we speak of team work and communal research. The simple apparatus of bygone days has given place to plant of an extensive and expensive character quite beyond the pocket of the ordinary individual, and because of this, the financial requirements of industrial research have to be seriously considered. The subject crops up at the meetings of every research association, and at the annual luncheon of the British Electrical and Allied Industries Research Association on February 12 provided the president, Mr. Ll. B. Atkinson, with a theme for his address.

The position of this particular Association, which was founded in 1920, is that though it is admitted it has done fine work with good results, yet the Department of Scientific and Industrial Research has had to announce that the grant to the Association for the next five years will be only half that given during 1920–25, while in 1930 it will be stopped altogether. Many of the leading technical journals have referred to this matter, and though it is generally regretted that the Department is withdrawing its support, yet there appears to be no doubt that the industry will rise to the occasion, find the whole of its own research fund, and probably benefit itself in so doing. The *Electrical Review* declares, "Research is no mere accomplishment, something merely ornamental; it is bedrock necessity," and "the partial withdrawal of Government aid must be accepted as a challenge to greater efforts." "Those who have saved large sums of money through the work of the Association know that it is so and ought to subscribe freely to its funds."

As to the position of the industry itself, it is a really active branch of engineering, and it has not had to go through the prolonged depression of many other branches. According to one return, the value of British electrical exports during 1925 exceeded those of both the United States and Germany, the figures for the three countries being: United Kingdom, 5,762,000*l.*; United States, 3,977,000*l.*; and Germany, 2,876,000*l.* From these figures it is evident that the withdrawal of the few thousands of pounds allocated to the Research Association by the Government can make no very appreciable difference to the volume of research if all in the industry are fully alive to the fact that research is a sound proposition commercially.

In the course of his presidential address at the luncheon at the Savoy Hotel, Mr. Atkinson referred to the lack of national interest and understanding of scientific matters, and towards the close of his remarks said: "Research Associations and research workers are not asking for charity; they are urging that the present squalid civilisation should be replaced, as it can be, by a far better one, if applied knowledge in every sphere is encouraged and developed; that instead of being a last charge upon the resources of the nation, research should be a first charge." In pressing his claims, Mr. Atkinson referred in eloquent words to the epoch-making discoveries and invention of British men of genius, and to Great Britain, "which in science has towered above all others." He remarked that "modern industrial and scientific knowledge is almost wholly the production of British effort." He mentioned the work of men such as Watt, Bessemer, Faraday, Davy, Kelvin, Lockyer, Newton, and Joule in glowing terms. Not only in practical mechanics, but also in mathematics, in chemistry and in physics, Britain had led the way. As to electricity, "the voltaic battery and the magnetic action of currents of electricity are not British discoveries, but that said we have finished," while "our fundamental discoveries have been carried forward and applied by hundreds of brilliant workers in all lands, but the claim that every great step forward in modern science is a British product cannot seriously be refuted."

No one of British birth fully aware of the achievements of the men of our race can fail to be proud of our record, but whether we are justified in regarding ourselves as the fount and origin of these things to the extent implied by Mr. Atkinson may be doubted, and some of his statements would, we think, be difficult to substantiate before an impartial tribunal. If one speaks of Dalton and Davy, it is not right to forget Lavoisier. If Perkins laid the foundation of the coal-tar colour industry, it is well to remember he gained instruction and inspiration at the hands of Hofmann, to whom English chemists owe a great debt. At one time British students eagerly sought the laboratories of Magnus and Bunsen and Liebig. What sort of history of physical science could be written without a mention of Kepler, Galileo, Huygens, Leibnitz, Euler, Lagrange, Fresnel, Fourier, Regnault, and Helmholtz?

Though we are aware of the brilliant work of Englishmen in many fields of discovery, we should be surprised to find a foreigner who would assent to Mr. Atkinson's estimate. Neither barometer, telescope, thermometer, microscope, air-pump, Leyden jar, thermopile accumulator, phonograph, or gramophone can be claimed for Britain. If we have had our Arkwrights and Cromptons, others also have had their Vaucansons and Jacquards. In practical chemistry the French can claim Berthollet and Leblanc, the Belgians Solvay, and the Germans Achard, Wöhler, and Welsbach. Our title to the steam engine and locomotive and the fundamental processes in iron and steel manufacture cannot be disputed, but once launched upon industrial development, the United States in some ways surpassed the mother country. In a well-written and balanced "Popular History of American Invention," which appeared a short time ago, the writers had evidently been to some pains to give honour to whom honour was due, but just as Mr. Atkinson claimed the carbon incandescent lamp for Swan and failed to mention Edison, so the American writer gave the credit to Edison and omitted to mention Swan!

There have been many causes contributing to British eminence in the worlds of science and engineering. Great Britain was never cursed by such a disaster as the Thirty Years' War, neither were the industries of the country subject to the grievous taxation due to the extravagances of a Louis XIV. The success of British arms and the spread of British commerce both influenced national development, while with its freer political institutions Britain has from time to time been the asylum of many able foreigners who have added their quota to the common stock of knowledge. Of these the great Herschel is the outstanding example, but other names, such as Mond, Siemens, Dollond, De Moivre, and Sprengel will be recalled. It is most desirable that, if lessons from history are to be used to stimulate inquiry, the historical views should be broad and just, for, as Davy remarked when presenting the Copley medal to Arago, "Science like Nature, to which it belongs, is neither limited by time or space. It belongs to the world and is of no country and no age." The British share in the spread of natural knowledge was admirably set out in "Britain's Heritage of Science" by two distinguished men of science, but that review does nothing to detract from von Zittel's remark that "all civilised nations have shared in the development of the natural sciences, the history of any one of which must be to a certain extent the history of a scientific freemasonry." While this is true enough, Mr. Atkinson was perfectly correct in showing that British achievements in pure and applied science have had world-wide influence in modern civilisation, and his address should serve a useful purpose in enlightening the public as to the fertility and power of British scientific genius and purposeful invention.

Simple Natural History.

(1) *The Life Story of a Badger.* By J. C. Tregarthen. Pp. xvi+152+8 plates. (London: John Murray, 1925.) 6*s.* net.

(2) *Round about Sussex Downs.* By Frederick F. Wood. Pp. 222+8 plates. (London: Gerald Duckworth and Co., Ltd., 1925.) 7*s.* 6*d.* net.

(3) *The Natural History of Hertfordshire.* By Dr. A. Wilmore, Albert N. Wilmore, W. Graveson, Richard Morse and W. Bickerton. Pp. viii+152+16 plates. (London: G. Bell and Sons, Ltd., 1925.) 2*s.* 6*d.*

(4) *More Chats on British Mammals: Rodents and Bats.* By Dr. J. J. Simpson. Pp. 125+4 plates. (London: The Sheldon Press; New York and Toronto: The Macmillan Co., 1925.) 2*s.* 6*d.* net.

(5) *The Unity of Life: a Book of Nature Study for Parents and Teachers.* By H. R. Royston. Pp. 281+16 plates. (London, Calcutta and Sydney: George G. Harrap and Co., Ltd., 1925.) 7*s.* 6*d.* net.

THE natural history of these small volumes is simple in the sense that it tends to confine itself to observations of first degree, and to avoid the more difficult ways of biological truth. This simplicity almost implies that its descriptions are of a kind made by many earlier observers, even where they have not been compiled from already existing sources of information. There is here, then, little that can be called new knowledge, but there is a great deal that is of interest to the general reader with a leaning towards natural history, and for such the books are intended. In their diversity they illustrate a noteworthy characteristic of natural science, the variety of avenues by which the subject may be approached; for although each is typical of a distinct class of treatment, any one might be taken as an easy introduction to the study of natural history.

Mr. Tregarthen's work (1) is an excellent example of the individual life-history. He traces with vividness and insight the adventures of one of the most interesting survivors of the old carnivore fauna of Britain, which he classifies in his own way—"scientists tell us that the badger belongs to the weasel tribe; to me, however, who am concerned more with its habits than its anatomy, it is a bear." In the course of his descriptions he brings out two very striking facts: the abundance of badgers in the Cornish district with which he is familiar—twenty-six earths from St. Ives to Land's End, averaging about one to every mile of coast, and eighty-one earths inland—and the extraordinary extent and ramifications of some of the century-old earths (one with forty-five holes), where many pairs of badgers repose in amicable security. It is gratifying to find that an English naturalist can avoid the tendency to a misleading anthropomorphism, which characterises a school (peculiarly American) of simple natural history, without sacrificing a whit of the interest of his story.

The nature essay is represented by (2). A series of disconnected chapters, with a geographical link, gathers up odds and ends of information which appeals to the lover of the country-side. The essays, which range from old country sayings to butterflies, bird life, foxes, dogs, hunting, coursing, etc., reveal great enthusiasm and close observation. Particularly interesting are the short chapters on tracks and tracking, and on the ingenuity displayed by hares in misleading hounds upon their scent.

A much more comprehensive treatise is the county natural history of Dr. Wilmore and his colleagues (3), in which are given simple accounts, adapted for school use, of the geology, physical geography, plant and animal life of Hertfordshire. Appendices to the sections suggest many promising experiments and exercises for the use of teachers and their pupils. The authors have wisely adopted a regional grouping of their information, for this affords an easy approach to the discussion of adaptation in both physical and biological spheres. The treatment in the latter sections, however, is unequal, and where 21 pages have been given over to mammals and 38 to birds, it is scarcely sufficient merely to mention that fishes, insects, and other invertebrates exist. The latter groups are not only of supreme importance to man, but they also form essential links in the chain of existence.

Dr. Simpson continues the systematic survey of British mammals (4), of which he has already issued one small volume. The present series of "ten-minute" broadcast "chats" contains concise yet well-balanced and wonderfully complete accounts of the appearance and habits of almost all the described species of British rodents and bats, special attention being directed to their human interest. The adoption of Latin systematic names as chapter headings is unnecessary, and must be repellent to many of the ordinary English readers for whom the book is intended.

Of our five types, "The Unity of Life" (5) is the most ambitious, for it essays to cover the field of general biology with a variety of purposes. It aims at assisting parents and teachers in imparting a systematic knowledge of nature-study, at educating the general reader who is interested in evolutionary biology, at instructing the elementary biologist in the wider principles of his science, and running throughout is the desire "to help all who are brought into close association with children to impart naturally and easily a knowledge of the main facts of the reproduction of life." The author finds it difficult to keep his balance upon these many stools. The foundation of his work is laid on a modified type system, for he discusses in detail the relationships of a few selected examples, and here his descriptions are all that is required. But the foundation is too narrow to bear the superstructure of biological principles which he would erect upon it, with the result that the treatment of the wider aspects is sketchy and incomplete. The book will probably appeal most to teachers of school biology who wish to make plain the vital connexion between the botanical and zoological sides of their nature-study.

Physiology for Clinicians and Students.

(1) *Clinical Biochemistry.* By Dr. Ivan Maxwell. Pp. 124 (interleaved). (Melbourne: W. Ramsay, 1925.) 12*s.* 6*d.*

(2) *An Intermediate Text-book of Physiological Chemistry: with Experiments.* By Prof. C. J. V. Pettibone. Third edition. Pp. 404. (London: Henry Kimpton, 1925.) 15*s.* net.

(3) *Bainbridge and Menzies Essentials of Physiology.* Fifth edition, edited and revised by Prof. C. Lovatt Evans. Pp. viii + 508. (London: Longmans, Green and Co., 1925.) 14*s.* net.

PERHAPS the most striking development of physiological knowledge in recent years has been on the chemical side, which has been due to a great extent to new and more accurate methods of analysis. Mention need only be made of the advance in knowledge of the oxidative process in muscle, of basal metabolism, of hæmoglobin, and of the ductless glands. It is important that this knowledge should be made available for the clinician as soon as possible. The clinician, however, cannot be expected to apply to his problems the elaborate methods which are necessary for scientific research, unless he can appeal to some-one with the necessary skill in a well-equipped laboratory. But since the chemical changes occurring in disease are often well-marked, methods which require but little apparatus or time for execution are sufficiently accurate to afford valuable information.

(1) The application of such methods to clinical work is well carried out in Dr. Ivan Maxwell's "Clinical Biochemistry." He has selected his methods with good judgment and has wisely refrained from making his book too large. Moreover, the book is not a mere reiteration of methods of analysis, for it is made interesting by some information about the diseases which lead to abnormalities in the blood and in the various secretions. The opening chapter on the urine is very well done, and is followed by an account of the estimations which can be made of renal efficiency. In this connexion we miss figures of urinary casts, glucosazone crystals, and of certain apparatus—in fact there are no diagrams at all. The book, however, is interleaved with blank sheets for the student to make his own drawings, and we think this is right. The chapter devoted to glycosuria is good, but might have been fuller with advantage, especially with regard to insulin. The estimations to be made in acidosis are well dealt with. There are welcome chapters on pancreatic efficiency and on hepatic efficiency, the van der Bergh's jaundice tests being given. There is also a very good account of gastric analysis—urinary sediments, calculi, variations in blood corpuscles and in hæmoglobin are all dealt with. The book can be safely recommended not only to the medical student but also to the clinician. A few slips have been left which would have been avoided by a careful revision of the proofs.

(2) Prof. Pettibone's text-book is a work of a very different character. It is divided into two parts, physiological chemistry and laboratory work. The latter part is the better, but some of the methods of analysis given are too elaborate for the clinician. The best chapters are those which deal with the proteins, the carbohydrates, the urine, and with blood analysis by Folia's well-known methods. The accounts of gastric and pancreatic digestion are scarcely adequate, for but little is given of the methods of testing gastric and pancreatic activity. The first part of the book is not well constructed; parts of it are quite elementary while other parts are highly technical and difficult. It must, however, be borne in mind that it is not easy to write a text-book on physiological chemistry, because it is almost impossible to say what processes are not chemical in the phenomena of life.

The book opens with a chapter on physical chemistry, with an account of hydrogen ion concentration and of colloidal solutions, and then deals with the chemical properties of the various substances connected with the animal body. All this is well done. The author then gives an account of digestion, bringing in scraps of knowledge about the processes of secretion and absorption, which are inadequate and some of them loose and inaccurate. It would have been better if these bits of physiological knowledge jumbled up with purely chemical matters had been omitted. There is a good chapter on protein metabolism, with an excellent account of the experiments initiated by Horace Fletcher, who, with his son-in-law, Dr. Van Sommeren of Venice, practised the chewing craze with such good results that several physiologists, notably Chittenden, investigated the effects of the low protein diet which the chewing leads to. Basal metabolism and vitamins, among other matters, are well dealt with, but this cannot be said of the treatment of the endocrine glands. The book will not seriously compete with those already published in Great Britain.

(3) It is gratifying to know that the editing of Bainbridge and Menzies' well-known text-book on physiology has fallen into the able hands of Dr. Lovatt Evans. This book has long supplied enough sound physiology for the unambitious medical student who has not the time or the ability to read one of the larger text-books. It is a pity that it has not been purged of some of its truly dreadful diagrams, such as that of the tracts in the spinal cord. Several other diagrams in the chapters on the nervous system are crude and inaccurate; Fig. 36, for example, is quite wrong and does not agree with the description in the text. The drawings of real structures, however, are clear and good, and several new ones have been introduced. It is difficult to decide how much histology should be introduced into a book of this kind. Yet Ranvier's drawings of degeneration and regeneration of nerve fibres are put in, without any drawings of normal nerve fibres. It would be impossible to point out the many little additions which have been made, but a notable one is the account of the work of Sir Gowland Hopkins and his school on tissue oxidations. The book has grown a little—it will defeat its purpose if it grows much more.

L. E. S.

Chemistry and Atomic Structure.

Chemistry and Atomic Structure. By Dr. J. D. Main Smith. Pp. 221. (London: Ernest Benn, Ltd., 1924.) 12*s.* 6*d.* net.

TO the author of this book belongs the credit of having been the first to suggest what appears to be the correct modification of the scheme originally proposed by Bohr for the distribution of electrons among the different levels and sub-levels in the atom. For example, in the completed *M*-level, according to this modification, in place of the 6.6.6-grouping of Bohr's original scheme, a 2.2.4.4.6-grouping is to be assumed. The probable correctness of this view is indicated by physical evidence, but the original presentation of it by the author was made in connexion with chemical considerations. A full statement of his evidence and reasoning, such as might be expected in this book, would therefore be exceedingly valuable, for it would be of the greatest interest to know whether the effects of differences in the electronic sub-grouping can be recognised in the chemical properties of the elements.

The first half of the book consists of an account of the development of the atomic and molecular theory from the speculations of Hindu and Greek philosophers to modern structural and stereo-chemical theories and the co-ordination theory of Werner; the second half gives an outline of some of the principal branches of atomic physics. It is in the last chapter that the deduction of the atomic structure of the elements from their chemical properties is considered, but the manner in which the evidence is presented is disappointing. It is difficult to gather from the statement there given a clear idea of what precisely the method is which has enabled the author to deduce the sub-grouping of the electrons from chemical facts. To take an example, he says: "The detailed chemical evidence, by which it can be shown that the first two valency electrons are differentiated in energy or firmness of binding from the third and fourth electrons, and that both of these pairs are differentiated from the remaining valency electrons, is so vast that no more than a tithe of this evidence need be cited to prove the point," and this is then given in the form of a series of chemical statements. But these statements have no obvious bearing on the question at issue. Thus the first is: "Cupric salts yield characteristically insoluble and stable di-pyridino-compounds." A careful explanation would be needed to show how this fact can be interpreted so that it can be brought into relationship with the detailed structure of the uncombined copper atom, but no explanation is given either of this or of the statements which follow it.

The difficulties involved on the electron-sharing theory of chemical combination in combining the two hypotheses: (1) that the maximum number of shared electrons is eight, and (2), that a single chemical bond always consists of two shared electrons, are discussed. The conclusion is drawn that the second hypothesis is to be abandoned, and the view is advocated that atoms are frequently linked through a single shared electron. (The author has further developed this view in a recent paper in *Chemistry and Industry.*)

It is then suggested that easily hydrolysable bonds contain only one electron whatever the valency of the atoms concerned. This, however, at once raises difficulties which seem to have been overlooked. For example, if the readily hydrolysable chlorine atom in the acid chlorides is linked through a single-electron bond, how are the remaining bonds of the carbon atom of the $-CO.Cl$ group to be interpreted?

The mechanism of electron-sharing is considered in an appendix. The possibility that the sharing is effected through the revolution of the electron in an orbit which encircles both nuclei is discussed in a passage that contains several errors, though in fairness to the author it should be stated that in the views which he expresses he is, in the main, following Prof. Morgan. The passage contains the following statements:

(1) "Obviously as such orbits have two foci of attracting nuclear charges, electrons cannot describe elliptic orbits." But it is well known that the ellipse is a possible and stable orbit for a particle revolving about two fixed masses situated at the foci.

(2) "The sections of equipotential surfaces about two equal similar charges [are] Cassinian ovals." (This statement is attributed to Clerk Maxwell.) Cassinian ovals, as is correctly stated, are curves in which the *product* of the distances of a point on the curve from the two foci is constant. But sections of the equipotential surfaces would only have this form in a field where the force varied inversely as the *first* power of the distance (as in that due to two parallel, infinitely long, straight, similarly charged wires). In the case under consideration it is the *sum of the reciprocals* of the two distances which is constant.

(3) If such a curve "is an orbit of constant potential [it is] consequently, a possible Bohr orbit for an electron." This inference is, of course, entirely unjustified. The simplest considerations show that neither Cassinian ovals nor the true equipotential curves are possible forms for the orbits.

There are other similarly unsatisfactory excursions into pure physics, including a theory of the ether which is claimed to elucidate the exchange of energy between electrons and radiation and the non-emission of radiation by an electron revolving in a Bohr orbit, discussions of the loss of mass associated with the loss of energy of a system, and a proposal that the orbital precession of an electron in the neighbourhood of other electrons should be regarded as taking place at right angles to the radius vector and the direction of motion. The ideas put forward in these passages are not in harmony with the spirit of modern physics, and in the opinion of the reviewer the author would have been well advised to have omitted them.

The treatment of the more purely chemical subjects is much less open to objection—though Werner's co-ordination theory is very doubtfully simplified by its presentation in the form of nineteen generalisations, and a good deal of space is devoted to the mechanical task of enumerating the types of isomerism that could occur among the derivatives of elements of the co-ordination number six.

Although there is thus much in this book which cannot be passed over without criticism, there is also much that is of merit and can be read with interest provided that the reader is already familiar with the subject. It gives a useful survey of several branches of chemistry, and some of the matter is presented in ways that are to a certain extent unusual and may provoke thought.

Our Bookshelf.

The Year-Book of the Scientific and Learned Societies of Great Britain and Ireland: a Record of the Work done in Science, Literature and Art during the Session 1924–1925 by numerous Societies and Government Institutions. Compiled from Official Sources. Forty-second Annual Issue. Pp. vii + 407. (London: Charles Griffin and Co., Ltd., 1925.) 15*s*. net.

It is a pleasure to be able again to extend a welcome to this valuable reference work. The issue before us, the forty-second, is about the same size as its predecessor, and its contents are arranged on the plan which has now become familiar: namely, the societies are grouped into fourteen main groups according to the subject of their activities, and under each group the London societies come first, followed by the provincial bodies, and finally those in Scotland and Ireland. Under each item are given details of the society's activities, publications, officers, address, and similar essential information. The word 'society' is interpreted very broadly, as the publishers are able to include Government institutions such as the Royal Observatory, Greenwich, the National Physical Laboratory, and so on, and in each case a brief but comprehensive account of the year's work and publications is given. It adds to the value of the work that the information given is compiled from data supplied by officers of the bodies concerned, and the fact that few entries are followed by the words "No Return" shows that these officers appreciate the labours of the publishers in the service of learning.

The proof of the value of an annual reference work such as this, however, is in the hands of those who are constantly using it, and we shall not be alone in affirming repeated indebtedness to its pages. For that reason, and to enhance its usefulness, we do not hesitate to refer to some omissions we have noted. The majority of the research associations are still omitted, and also we have found no reference to the Society for the Preservation of the Fauna of the Empire, the British Institute of Philosophical Studies, the Institution of Welding Engineers, or the newly-formed Electroplaters' and Depositors' Technical Society. Nevertheless, we have no doubt that a year hence the volume will show similar signs of honourable service to those which now mark earlier issues.

The Essentials of Mental Measurement. By Dr. William Brown and Prof. Godfrey H. Thomson. (The Cambridge Psychological Library.) Third edition. Pp. x + 224. (Cambridge: At the University Press, 1925.) 17*s*. 6*d*. net.

The latest edition of this book contains a new chapter dealing with the present position in the controversial question of the relation between general and special abilities. In many respects this is the most interesting chapter in the book. Following a critical survey of Prof. Spearman's two-factor theory, Prof. Thomson enunciates his well-known sampling theory of ability, and proceeds to show that the two theories are not mutually destructive, that, on the contrary, in certain circumstances the differences between them are not nearly so fundamental as might be thought. It will be a source of encouragement to the non-mathematical student of these problems to learn that, while there are still vital differences between the various views, there is a movement towards agreement. The results of present investigations which are expected to settle some outstanding differences will be awaited with interest.

Meanwhile, it is perhaps significant to note that in some quarters there is an increasing tendency to approach the question from other directions. One feels that the study, with the aid of elaborate mathematical devices, of data derived from comparatively crude experimentation, is useful only within certain limits. This is, to some extent, confirmed by the note of caution maintained by the authors in regard to conclusions to be derived from the statistical study of mental measurements, especially from correlation coefficients. In this connexion it would be useful if the note on Kelley's *coefficient of alienation* were further developed in a later edition. In the main, however, the book remains unaltered, and contains, besides a well-developed statement of Prof. Thomson's own views, sections on the psycho-physical methods and the theory of correlation. Some new footnotes bring the book up-to-date.

Aphrodite aculeata. By Mahalah G. C. Fordham. (Liverpool Marine Biology Committee Memoirs on Typical British Marine Plants and Animals, 27.) Pp. viii+96+10 plates. (Liverpool: University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd., 1925.) 5*s*. net.

A SYSTEMATIC description is given of the external features of Aphrodite, of its respiration, and of the circulatory, digestive, muscular, excretory, reproductive, and nervous systems. The lobules of the 'cephalic nerve centre' (*i.e.* the cerebral ganglia) and the associated nerves are described in some detail, but there is no figure illustrating the external topography of the centre. A giant cell from the ventral nerve cord is figured without any comment as to whether any other giant cells occur and whether giant fibres are present. A short account of the structure of the eye might have been added. In our opinion, too much is made of small differences between the types of cells in the cæcal epithelium; there are said to be eleven types, but it would be difficult to justify more than half of them. We note that many of the papers cited under "Literature" are not referred to. We must enter a dissent against 'plexi' as the plural of 'plexus,' and 'nuchal' is better than 'nucal,' which is used in the work.

The eight plates contain a useful series of figures. The text-figure of a parapodium of Nereis was evidently intended to show the outlines of the setal sacs, for reference letters are given in the text below the figure, but the outlines have been omitted. An indication of the magnification of the setæ shown in text-fig. 3 would have been helpful.

The examination of the external features and internal anatomy of Aphrodite forms part of the second year course in many laboratories, and hitherto no comprehensive account has been available. Miss Fordham has put a good deal of work into the preparation of the memoir, which will serve as a helpful guide to the study of an interesting polychæt.

Recent Advances in Physiology. By Prof. C. Lovatt Evans. Pp. xi+364. (London: J. and A. Churchill, 1925.) 10*s*. 6*d*. net.

IN a book covering recent advances, it is interesting and important to observe how the space has been allotted between the different fields of work. In this case Prof. Lovatt Evans has made a dull beginning with 90 pages on blood. The work on muscle by A. V. Hill and Meyerhof has been given 80 pages; work on circulation rate (Barcroft, Douglas, Krogh) and Starling's heart-lung preparation, 40 pages; Hopkins and Warburg on tissue oxidations, 30 pages; Krogh and Dale on capillary circulation, 30 pages; Magnus on postural reflexes, 30 pages; Pavlov on conditioned reflexes, 30 pages; finally the cheaper sensations of the endocrine world have some 20 pages.

It will be clear that this small volume is astonishing in its scope, yet there is much evidence that the author has carefully digested his sources of information, so that the presentation is logical and interesting. Even amid the technicalities of the mechanics of muscular contraction, he writes in such a way as to make it comprehensible to the reader. The accounts of the work of Pavlov and Magnus are particularly valuable, as there is no other general account of these in English.

It is difficult to exaggerate the importance of a book of this type, if it is short and good, for it plays a considerable part in deciding the questions to be asked in honours examinations during most of the next decade. By its means the habitual examiners bring themselves up-to-date, and it soon is responsible for the subjects studied by the students. Prof. Lovatt Evans' book will play an extremely valuable part in this direction, and it is fortunate that Messrs. Churchill should have persuaded a scholar at once so fundamental and clear-headed to write it.

A Graduated Course in Strength and Elasticity of Materials. By Edward Percy Coston. (Broadway Engineering Handbooks, Vols. 37 and 38.) Vol. 1. Pp. xii+264. Vol. 2. Pp. xii+436. (London: Scott, Greenwood and Son, 1925.) 10*s*. 6*d*. net each.

THESE two volumes were left in MS. by the late E. P. Coston, of the Engineering Department of the University of Liverpool, and were prepared for publication by students and colleagues upon the staff. It was a work worth undertaking, for the two volumes reflect the thought and experience of a good teacher. Most treatments of strength of materials incline either to be a practical compendium of engineering data more or less critically connected, or a mathematical analysis of the elastic properties of simple geometrical forms more or less divorced from reality. Both these snares are here avoided. In preparing this book, the author had in mind the average engineering student and his growth in knowledge of the subject. The work is arranged so that the elementary part is covered in vol. 1, in which the simple theory is interwoven with a critical discussion of elastic data. Each part of vol. 1 is developed to a more advanced stage in vol. 2. Copious examples graduated in difficulty and many of them worked out in detail are a distinct asset to the work.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Motion of Radiating Masses and the Effect of Radiation Pressure.

THE equation of motion of a body which is losing mass by the emission of radiation is

$$m\frac{dv}{dt}=F, \quad . \quad . \quad . \quad . \quad (1)$$

where m is the momentary mass of the body and F the applied force. The simplest justification for this equation is found in the principle of relativity, which requires that v shall be constant when $F=0$.

In NATURE of February 27, p. 300, Sir Joseph Larmor suggests that considerations of inertia would seem to require the equation

$$\frac{d}{dt}(mv)=F, \quad . \quad . \quad . \quad . \quad (2)$$

and finds an apparent paradox in the incompatibility of this with my equation (1). The paradox disappears as soon as it is noticed that equation (2) ignores the momentum carried away by the shed mass. In time dt the momentum mv experiences a gain Fdt from the action of the force F, and a loss $-v\frac{dm}{dt}dt$ through the shedding of the mass $-\frac{dm}{dt}dt$. Thus

$$\frac{d}{dt}(mv)=F+v\frac{dm}{dt},$$

which is equivalent to my equation (1).

Either of these quite simple arguments appears to decide the question in favour of my equation (1), and this by a conclusive verdict, not the mere "adequate practical settlement" of Sir Joseph Larmor.

Sir Joseph further suggests that the aberration effect of radiation pressure may be of importance in the dynamics of binary systems. Calculation scarcely supports this view. In the average binary orbit the force exerted by radiation pressure is about 10^{-13} times that exerted by gravitation, and the tangential force is v/C times this, or say 10^{-19} times the force of gravitation. The cumulative effect of this force might become serious as the number of revolutions of the system approached 10^{19}, but binaries do not live long enough for this to happen, and the actual effect must be negligible.

Consequently I adhere to the solution I originally gave (*Monthly Notices*, November 1924 and October 1925) for the orbit of a radiating binary. The orbit is an ellipse, the shape of which undergoes no change but the dimensions of which steadily increase as the mass wastes away, the product of the mass and the diameter of the orbit remaining constant. For example, the sun's wastage of 250 million tons a minute to produce radiation must result in an expansion of the whole solar system; the diameter of the earth's orbit increases by two centimetres per annum, those of the other planets, comets, and meteorites expanding in exact proportion. If higher accuracy than this is called for, dynamical factors arising from tidal friction and elongation of mass seem likely to have more importance than pressure of radiation.

J. H. JEANS.

February 27

The Spectra of the Neutral Carbon Monoxide Molecule.

WE can now claim to have a fairly extensive knowledge of the radiation of the ionised carbon monoxide molecule CO^+. The three associated spectra, namely, Deslandres' first negative bands, the comet-tail bands, and the associated system (*vide Proc. Roy. Soc.*, A, vol 108, p 349) have been discussed by Prof. R. T. Birge and others, and in particular by Dr. Mulliken in an excellent comparative study with other typical one-valence electron emitters (*Phys. Rev*, ii. 26, p. 561).

With regard to the spectra of neutral CO, I have recently been investigating some carbon spectra, arranging them in series, and assigning vibrational quantum numbers, and the results of this are presented in the present communication. About the time I had discovered the relationships referred to below, I had a communication from Prof. Birge in which he informed me of the substance of some of his work (published since in NATURE of February 13, p. 229). As my own findings are related to those of Prof. Birge, I am able through his kindness to correlate some of these results with mine; and these, together with a discussion of their significance, are given in this letter.

In a paper entitled "The Effect of Neon on Certain Spectra" to be published shortly in the *Phil. Mag.*, Mr. Cameron has given the wave-lengths of a new band-spectrum associated with carbon, the conditions for the production of which seemed to be peculiarly favourable in high-pressure neon. The spectrum lies between about λ2100 and λ2600, and falls into three or four groups having about five bands in each. Each band, however, is complex, being composed of five distinct sub-heads, and resembling the complex bands of the third positive carbon system or the fourth positive nitrogen system. I have made a quantum analysis of the above system and give it below (where only the second member of the quintuple heads is recorded for simplicity, *vide* Table I.).

TABLE I.

n'/n''	0	1	2	3	4	5	6	7	8
0	..	Present	44,244	42,160	40,102	..	..	..	..
1	..	..	Present	43,875	41,809	39,770	..	..	..
2	..	..	..	Present	Obsc.	41,457	39,444	..	..
3	..	..	..	..	..	..	41,099	39,113	.
4	..	..	..	..	..	..	..	40,739	38,783

Even under the most favourable conditions the system is not very strong, and Mr. Cameron suggests that his errors of wave-length may perhaps be so much as 0·5 Ångström units. I find that the system can be represented by

$$\nu=K+(1728{\cdot}2\,n'-14{\cdot}6\,n'^2)-(2151{\cdot}7\,n''-12{\cdot}7\,n''^2),$$

where n' and n'' are initial and final quantum numbers, and K has the values 48534·3, 48496·5, 48478·2, 48461·0, and 48431·2.

Prof. Birge has informed me that the fourth positive carbon bands are completely represented by the formula

$$\nu=64721+(1499{\cdot}28\,n'-17{\cdot}24\,n'^2)$$
$$-(2147{\cdot}74\,n''-12{\cdot}703\,n''^2),$$

and that they are the 'resonance' band system of CO as shown by Leifson's absorption work in the extreme ultra-violet.

It is clear, therefore, that within the limits of experimental error Cameron's bands and the fourth positive carbon bands have the same final electronic state, which is the normal state of the carbon monoxide molecule.

Prof. Birge has informed me further that the Ångström bands are represented by

$$\nu=22162+(2158\,n'-76\,n'^2)-(1499{\cdot}28\,n''-17{\cdot}24\,n''^2),$$

so that we have the interesting relation that the final state of the Ångström band emitter coincides with the initial state of the fourth positive carbon emitter.

I have discovered an analogous relationship by a quantum analysis of the third positive carbon bands, namely, that the final state of the third positive band emitter is coincident with the initial state of the emitter of Cameron's bands. The available measurements of the third positive carbon system are not good, so that any formula representing them is necessarily very approximate. I have, however, calculated roughly

$$\nu = 35300 + (2258{\cdot}5\,n' - 48{\cdot}5\,n'^2) - (1728{\cdot}2\,n'' - 14{\cdot}6\,n''^2)$$

for purposes of the completion of Table II. The main series, which is $n' = 0$, $n'' = 0$ to 5, permits of no doubt whatever of the above identification of the initial electronic state of Cameron's bands and the final electronic state of the third positive system. The multiplet structure of the common vibration levels is very conclusive. The best values of the separations in wave-number units are:

Cameron's bands : 37·8, 18·3, 17·2, 29·8
Third pos. carbon : 36·4, 17·4, 17·8, 29·6.

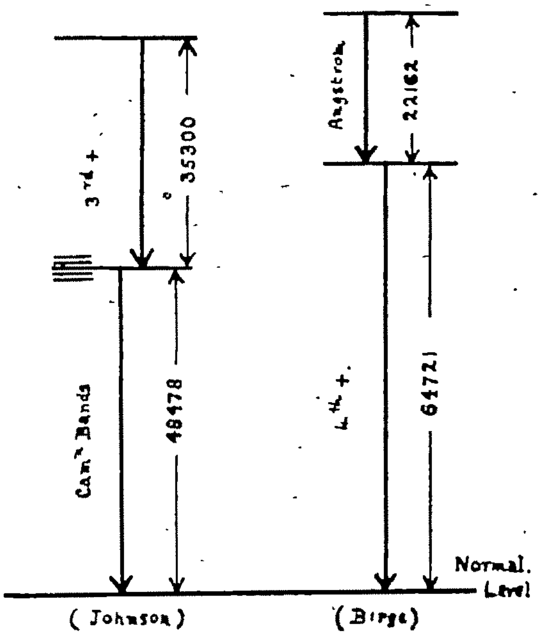

FIG. 1.—Energy levels of the neutral CO molecule.

This agreement is well within the limits of error. The relative intensities of the sub-heads correspond in both systems. It seems just possible that there may be six levels in reality, making the intervals in the case of the third positive system 8·8, 27·6, 17·4, 17·8, 29·6, but this head being fainter than the others would not be visible in the Cameron system. The question is important from the point of view of discussion of multiplicity in band spectra. It may be that the quintuplet is a characteristic of 2-valence electron emitters. We have the analogous fourth positive nitrogen structure in the case of N_2. With this in view I have examined Dr. Jevons's reproduction of the spectra of silicon oxide and aluminium chloride (*Proc. Roy. Soc.*, A, vol. 106, p. 174), which should present analogies, but I have not been able to arrive at any definite conclusion. The spectrum of silicon chloride shows doublet separation characteristic of the 1-valence type.

In view of Birge's work on the energy levels of the neutral nitrogen molecule (NATURE, November 1, 1924, and January 16, 1926), we now have the material for an interesting comparative study of two very similar molecules, CO and N_2. This, together with the above questions, is reserved for fuller discussion elsewhere.

Our knowledge of the neutral carbon monoxide molecule is summarised in the diagram, Fig. 1, and in Table II.

TABLE II.

Emitter.	*Spectrum.*	ν_e	*Excited State.*		*Normal State.*	
			(a')	(b')	(a'')	(b'')
CO	Cameron's	48,478	1728·2	14·6	2152·1	13·7
	3rd Pos.	35,300	2258·5	48·5 ?		
	4th Pos.	64,721	1499·28	17·24	2147·74	12·703
	Ångström	22,162	2158	76		

With regard to the possibility of identification of the initial levels of the third positive system and the Ångström bands, which are not very different, it does not seem possible to pronounce finally until more complete measures of the third positive bands are available. With regard to the latter, I have found that apparently the initial states $n' = 0$, 1, and 4 are present, while $n' = 2$ and 3 are absent (incidentally, this curious probability distribution in the various vibrational states is quite a common phenomenon). I intend to discuss this elsewhere. I am afraid the weight of evidence at present is against the identification of the above initial energy levels. The two values 10·34 volts and 10·73 volts may possibly be identified with the ionisation potential 10·1 volts (Foote and Mohler) of CO, but if so, this raises the identification difficulty.

With regard to Table II., I must be content merely to record the facts and discuss them fully elsewhere. As with 1-valence electron emitters, the greater stability of the second excitation level in comparison with the first may be noted.

Excepting the fourth positive bands, which must now be attributed definitely to CO, the surmises of a previous letter (NATURE, October 10, 1925) based on experimental evidence as to the CO origin of Cameron's bands, the Ångström bands, and the third positive bands are now seen to be confirmed.

Contrary to the views some have held, it seems doubtful if we can attribute *any* spectra to a carbon dioxide molecule. This would harmonise with its structure, which is of the 'inert gas type' and may not be expected to radiate (cf. BN). For similar reasons the silicon oxide and titanium oxide band spectra are probably due to SiO and TiO and not to SiO_2 and TiO_2. This may, therefore, have an important bearing from a thermo-chemical point of view on the temperature of the titanium oxide stars.

The Constancy of Atomic Weights.

THE natural desire we have to attain finality in argument or experiment is usually helpful to progress but sometimes needs restraint. Believing such a need to exist in current thought upon the subject of this letter, we enter a plea for the retention of an open mind as to whether, in fact, elements as they naturally occur have always and everywhere the same atomic weight. The problem is evidently of fundamental importance, and its elucidation is likely to be hindered if chemists generally regard it as solved. We can the more easily ask for judgment to be reserved, as work done in these laboratories has provided the best evidence yet available for both constancy and variability in atomic weight.

Determinations of the ratio of boron trichloride to silver carried out by the writers in 1924 afforded purely chemical evidence that samples of boron from widely separated sources differed in atomic weight by about 0·02 unit (*Journ. Chem. Soc.*, 1925, 127, 696). Later determinations of the density of boric oxide from the same and other sources disclosed differences in density which in sign and magnitude confirmed the variations in atomic weight previously found (*ibid.*, 1926, 128). While we are unable to trace any flaw in this work, we have expressed our view that, in such a matter, it is unsafe to base conclusions on any one set of researches and that independent work is urgently needed.

At about the same time, Jäger and Dijkstra (*Versl. Akad. Amsterdam*, 1924, 33, 333; *Proc. Acad. Amsterdam*, 1924, 27, 393; *Zeit. anorg. Chem.*, 1925, 143, 233) seeking to ascertain, by purely physical means, whether or no the atomic weight of silicon were constant, prepared tetraethyl silicane from six terrestrial sources and six stony meteorites, compared the densities of the samples by a pyknometer method. They record in their paper the observed densities and the corresponding differences in the atomic weight of silicon. This method of stating the results may evidently give an erroneous impression of their precision, because Dr. Aston (Annual Reports on the Progress of Chemistry, 1924, 21, 243) was led to describe this as a "conclusive paper" affording evidence "that the ratio of the isotopes of silicon is constant within the limits of the highest accuracy attainable at present." We have, therefore, calculated the actual atomic weights of silicon corresponding with the observed densities, making the assumption, obviously reasonable and good enough for comparative purposes, that the mean observed density of tetraethyl silicane = 0·767349 corresponds with the most probable value of the atomic weight of silicon Si = 28·060. From these values it is at once apparent that the maximum and minimum values are 28·051 and 28·060, with a difference of 1 part in 1477. When we remember that many atomic weights have an uncertainty much less than 1 part in 5000, it is difficult to justify the terms "conclusive" evidence and "highest accuracy attainable" quoted above.

We are aware that Jager and Dijkstra observed that the refractive index of their samples of tetraethyl silicane showed a variation corresponding with the variations in density, and hence concluded that the latter were, at least in a great part, due to varying traces of impurity, but we believe that this argument is fallacious. There is no direct evidence on the point, but it seems not unlikely that an increase in the proportion of a heavier isotope of silicon in a silicon compound would increase the refractive index of that compound, just as, say, substitution of barium for calcium increases the refractive index of glass.

It happens that during the last three years we have been engaged in preparing to make a re-determination by chemical means of the atomic weight of silicon using, as in the case of boron, samples from widely separated known sources. In the course of this work the opportunity has arisen for one of us to make a careful comparison of the densities of samples of silicon tetrachloride prepared from these sources and subjected to the same very rigorous process of purification. From these densities it is possible to deduce values for the atomic weights of silicon which show a maximum difference of 0·005 unit. These density figures will, we hope, be published shortly, and we give here simply the atomic weights deduced from them together with those cited earlier in this letter.

TABLE.

ATOMIC WEIGHTS OF BORON AND SILICON.

Boron.		Silicon.	
Briscoe and Robinson.	Briscoe, Robinson and Stephenson.	Jager and Dijkstra.	Robinson and Smith.
		Terrestrial 28·051	28·059

Hybridity, Parthenogenesis, and Segregation.

IN a recent paper entitled "On Parthenogenesis originating in Lepidopterous Crosses" (*Trans. Nat. Hist. Soc. of Northumberland, Durham and Newcastle-upon-Tyne*, N.S., 6, Part II.) we discussed certain hybridity experiments between the geometrid moths *Tephrosia crepuscularia*, Bkh., and *Tephrosia bistortata*, Goeze, both of which species had been previously proved to be non-parthenogenetic; in that work conclusions were set out which may be briefly summarised as follows:

(1) These two species cross readily, yielding hybrids which are fertile *inter se* and fertile also when back-crossed on either parent; this fertility continues unimpaired when any of these hybrids are continuously inbred.

(2) Several unmated females, the outcome of crossing *T. crepuscularia* ♀ ♀ and *T. bistortata* ♂ ♂, deposited eggs freely, and in certain cases a small percentage of their eggs developed parthenogenetically.

(3) From these facts we concluded that there was some relation between parthenogenesis and hybridity which, in our opinion, was one of cause and effect.

(4) Specially noteworthy was the fact that the parthenogenetic offspring showed segregation in respect to wing colour, pattern and sex.

These results are of importance inasmuch as the thesis that parthenogenesis could be induced by hybridity had been advanced by Ernst (1918) on theoretical grounds in his "Bastardierung als Ursache der Apogamie im Pflanzenreiche," and accepted by Täckholm, Holmgren and others as a satisfactory explanation of the observed facts in critical genera like Rosa, Erigeron, etc. Whilst we agreed generally with this position, we felt, and therefore stated, that a rigid proof of its validity was lacking, *i.e.* the experimental production of an apogamous hybrid from parents conclusively shown to be non-apogamous had never been achieved.

Our experiments, curiously enough from the zoological side, provided the desired case and we had thought that they were unique. Recently, however, we received papers from Prof. Nabours, Kansas State Agricultural College, which recount his painstaking genetical experiments with grouse locusts (1919, "Parthenogenesis and Crossing Over in the Grouse Locust Apotettix," *Amer. Nat.*, 53, No. 625; 1925, "Studies in Inheritance and Evolution in Orthoptera, V. The Grouse Locust *Apotettix eurycephalus*, Hancock," *Technical Bulletin* 17, Kansas State Agr. Exp. Stn., Manhattan), and afford welcome support to our work. This aspect, however, does not seem to have occurred to Prof. Nabours.

From his 1925 paper (p. 229) Prof. Nabours' conclusions may briefly be quoted: (1) "The members of the species *Apotettix eurycephalus*, Hancock, are bisexual, the fertilised eggs producing males and females in equal numbers, and parthenogenetic, the unfertilised eggs, with rare exceptions, hatching females . . .," and (2) in respect to colour and pattern and, to a less extent, in sex, he asserts "the segregation of factors occurs in individuals producing parthenogenetically apparently to the same extent as in those reproducing bisexually."

Nabours believes that "segregation and crossing over occur before the inception of the parthenogenetic processes," and as a possible explanation of his results, that "the chemical changes which take place during the wait of the pronucleus, in the absence of fertilising sperm, furnish the stimulus to parthenogenesis." Further, he seeks to explain his homozygotes by various hypotheses demanding the doubling of chromosome number.

In view of the essential similarity of these results of Nabours and ours, we consider that one explanation may cover both sets; in short, the solution suggested lies in hybridity.

This opinion receives weighty support from evidence we adduce from Prof Nabours' own papers. In the second (1925) paper he writes (p. 7): "Messrs. Rehn and Hebard[1] have examined specimens of these and definitely determined that they belong to the same species (Nabours, '19)." Turning to the 1919 paper, we find in a footnote (p. 131), "Identified by Mr. Rehn as *Apotettix eurycephalus* Hancock, and by Doctor Hancock as follows: 'nearer the Mexican species *Apotettix convexus* Morse, than the nearly allied Texan species, *Apotettix eurycephalus* Hancock. *Inasmuch as you have used material from both Texas and Mexico in your experiments, it is possible you have hybridised the two* . . .'" (italics ours). Investigations into Prof. Nabours' pedigree tables of the females used in parthenogenesis show that the ancestors can be traced to both stocks, the Texan and the Mexican.

Recognising the implication in this footnote, we submit, therefore, that Prof. Nabours, in supplying from a different group of insects this additional example of segregation under parthenogenesis, has also furnished, although he has not appreciated the fact, a case of parthenogenesis consequent upon hybridity.

[1] Hebard is obviously a misprint for Hancock, who is cited as one of the authorities in Nabours' 1919 paper.

Measurement of the Discharge of the Blue Nile through the Sluices of the Sennar Dam.

WHEN the Aswan Dam was completed in 1902, very little was known about the discharge of large sluices of the type constructed at Aswan. By means of a large tank of 22,000 cubic metres capacity, the discharge of one type of sluice 3·5 metres high by 2 metres wide was determined for discharges ranging from 1 to 96 cubic metres per second and for heads up to 13·5 metres above the sill. The discharges of other types of sluice were then compared with those of the standardised type by means of the river level. Thus the discharge of the Nile at the important time of the year is known for monthly periods with a probable error of about 0·6 per cent. (For an account of this see MacDonald and Hurst, *Min. Proc. Inst. C.E.*, Paper No. 4350, 1921.)

The fundamental tank measurements were used as a standard with which to compare the discharges of a series of scale models of the experimental sluice. It was found that the ratio of the discharge of the large sluice to that of its model was closely $n^{\frac{5}{2}}$ where n is the ratio of their linear dimensions. The mean departure of the ratio of the discharges from $n^{\frac{5}{2}}$ using six models and three different scales over a wide range of conditions was 0·4 per cent., and the largest departure for a group of experiments on one model was 4·6 per cent. The condition throughout was that of free discharge into air. (For an account of this work see Hurst and Watt, *Min. Proc Inst. C.E.*, Paper No. 4450, 1924.) The above experiments show that models can be used to predict the discharge of large works, and this is borne out by many experiments made at the Delta Barrage, Egypt, by Mr A. D. Butcher with models of weirs and regulators.

Another result of the fundamental measurements of the river at Aswan was to show that discharges measured by current meters of the Price pattern agree closely with the results of tank measurements, for ordinary velocities of flow. The mean value of (sluice - current-meter) for measurements during the low stage of the river for 3 years is 0·2 per cent.

I have recently completed a series of experiments on a model, scale 1/50, of one of the sluices of the new Sennar Dam on the Blue Nile. These sluices are 2 metres wide and 8·4 metres high, and will discharge under varying conditions of upstream and downstream head, having sometimes a small depth of water above the sill downstream and being at others completely submerged downstream. The discharge of the Dam sluices has been deduced from the model experiments for all conditions. Since the filling of the reservoir was started last July, a variety of conditions has occurred. During this time the discharge of the river has been measured downstream of the Dam every few days by means of a current-meter. It is interesting to state that a comparison of the discharges measured by current-meters and those deduced from the sluices shows that there is good agreement between them. Thirty-five discharges are available, and the mean result deduced from the model experiments is about 3 per cent. greater than that deduced from the current-meters. This may be modified slightly when the current-meters are re-rated.

These results show the value of model experiments. Their principal value is that though they cannot be relied upon to give results in which the systematic error is less than 5 per cent., the accidental errors are small. For many purposes an accuracy of 5 per cent. would be good enough. However, when once the systematic error has been found from a few current-meter measurements well distributed over the whole range of practical conditions, the model can be used to give the discharge of a sluice under any conditions of upstream and downstream level and sluice opening within the range of practical conditions. Information thus becomes available with very little labour which would otherwise take many years and great expenditure of money to collect. In the case of the Sennar Dam, the resident engineer has a table of the discharge of the sluices from the commencement of the working of the Dam, upon which he can base his regulation of the river. Without the model results he would have had to experiment for years after the completion of the Dam before he could have constructed a discharge table for the sluices.

The Fundamental Level of the Iron Atom.

THERE is still some difference of opinion about the fundamental level of the iron atom. From Laporte's analysis (*Zeit. für Physik*, 23, 135, 1924) it appears that the chief lines proceed from five fundamental levels, constituting a quintet *d*-group. But this is at variance with the experiments of Stern and Gerlach on the directional quantisation of atoms. Gerlach states that there is a group of strong lines at about λ = 2100 Å.U., which are not included in Laporte's classification. But Laporte, in support of his view, states that the ^5D group for iron fits best with the rule given by Catalán on the normal orbits of the elements of the transitional series from potassium to nickel (*Journ. Opt. Soc. America*, November 1925). Laporte further states that his point of view "is favoured by some astrophysical facts, and by the almost complete classification of the lines of iron, which now makes it improbable that any important low terms are unknown." I am not aware of the astrophysical facts which Laporte has in view, but such facts as are available to me seem to favour the other view.

In the absorption experiments of Grotrian and Gieseler (*Zeit. f. Phys.*, 22, 245, 1924), the strong group of $^5D - {}^5D'$ lines of the iron spectrum was obtained in absorption at 1250° C., so that this experiment may be interpreted as deciding against the existence of a higher *s*-term. But we cannot hold this sort of evidence to be decisive, because at this temperature of the furnace it is quite possible that a large amount of ^5D-orbits are produced. Once they are produced they will remain fairly stable, for the transition $D \longrightarrow S$ being forbidden, the *D*-states will be metastable. This is supported by evidence from the chromospheric spectrum. The strongest lines in the iron spectrum, λ = 3856·46 and λ = 3860·01, reach in the solar chromosphere a height of 6000 km., and Evershed (*Phil. Trans.*, 201, 470) notes that they are intensified from intensity 8 (Rowland's scale) in the Fraunhofer spectrum to 15 in the flash spectrum, and this behaviour is typical of lines arising from metastable orbits.

Miss Payne in her recent monograph on stellar atmospheres (Harvard Observatory Monographs) has traced the behaviour of iron lines in different classes of stellar spectra. Unfortunately, she has not treated the behaviour of $^5D - {}^5D'$ lines of iron, but of $1{}^5D - 1{}^7F$ lines. These are intercombination lines, and should therefore be strengthened at lower temperatures. At any rate, they enable us to trace the behaviour of Laporte's fundamental (^5D) levels in stellar atmospheres. Miss Payne states that these lines reach a maximum in the *K*2 type of stars. According to the theory of Fowler and Milne this is typical of the behaviour of lines arising from subordinate series. So the astrophysical evidence seems to indicate that ^5D's are subordinate levels. But in order to be certain on the point, the behaviour of either the $^5D - {}^5F$ group lying at about λ = 3700 Å.U. or the $^5D - {}^5D'$ group ought to be traced in stellar atmospheres. The stellar data in this region are not very satisfactory.

Laporte's second point of contention, that the almost complete classification of the iron spectrum makes it improbable that any important low terms are unknown, cannot be regarded as conclusive, and I will illustrate my point by an analogy from the spectrum of neon. All the strong lines of neon obtained within the range λ = 2000 Å.U. to λ = 8000 Å.U. have been classified by Paschen into series, and it has been shown that there are four *s*-levels, denoted by him as s_2, s_3, s_4, and s_5. There are apparently no strong lines left outside Paschen's scheme of classification, yet we now know that these four *s*-levels do not constitute the normal level of neon, because it is perfectly transparent to all radiation from λ = 2000 Å.U. to λ = 8000 Å.U. in the unexcited state. As a matter of fact, Hertz (*Zeit. f. Physik*, 32, 933, 1925) has discovered two strong lines at λ = 735·7 ± 0·5 Å.U. and 743·5 ± 0·5 Å.U., and finds that these can be represented by $x - s_2$ and $x - s_4$. Goudsmit (*Zeit. f. Physik*, 32, 794, 1925), rediscussing the whole data on neon, including Landé's system of grouping the neon series, finds that the term x may be regarded as a singlet *S*-term, having the inner quantum number 0, while Paschen's s_2 is a *P* term of the singlet group, having the inner quantum number 1, and s_3, s_4, s_5 constitute the *p* terms of a triplet group, having the inner quantum numbers 0, 1, 2 respectively.

Here we have the undoubted evidence of the existence of a normal term s_0, which does not give rise to any one of the familiar strong lines of neon. It is now recognised that the spectra of elements having a large number of electrons in the outer ring have more or less a neon-like structure, and if iron, nickel, or cobalt have a still lower fundamental term *s* or *p*, it would not be responsible for any strong lines in the usual range. To find this term, the spectrum in the Schumann region must be very thoroughly investigated, and then only can the point be settled.

The Constitution of the Heaviside Layer.

IN the issue of NATURE of September 5, 1925, p. 357, Messrs. Breit and Tuve give a method for determining the height of the Heaviside Layer at night. It consists essentially in transmitting a series of impulses and recording them on a receiver at about 7 miles distance. Two groups of impulses were obtained, the time interval between two successive impulses giving the difference in time taken to traverse the two paths, one going direct to the station, and the other by the indirect path up to the Heaviside and back. From the results a height of about 80 km. was deduced.

The authors state that other experiments were tried on a 600 metre wave-length over distances of 100 to 150 miles, but these gave no definite results, there being, I presume, no second impulse due to the indirect ray.

The object of this letter is to point out a possible reason for this failure. At these distances the indirect ray strikes the Heaviside layer at practically 45°, assuming the height of 80 km. is correct. Now if the constitution of the layer is one in which there are free ions and electrons, the pressure being so low that the average time between collisions is large compared with the time period of the waves, a constitution which from other experimental evidence we have reason to expect, and if the wave is polarised with the electric force in the vertical plane, nothing will be reflected at 45° incidence. This angle is in fact the polarising angle of the layer, and is independent of the frequency, and moreover does not depend on how the layer is graded, that is, whether it is a gradual or a sharp transition. Under these conditions only the direct ray will be received, the indirect ray not being reflected.

If this reasoning is correct the results obtained over these distances constitute not only a rough confirmation of the height measurements, but also of the assumed constitution of the layer.

British Chemical Glass.

Prof. W. E. S. Turner, of the Department of Glass Technology in the University of Sheffield, in a letter to the *Times* of February 15, stated that " this industry . . . owes its inception to Sir Herbert Jackson and the hearty co-operation of several glass manufacturers in 1914 and 1915." I am sure that Sir Herbert Jackson would regret that the sole credit should be given to him and no mention made of Prof. Meldola, the chairman under whom he worked, and I trust, therefore, that Nature will be able to find space to correct a statement so deficient as that made in the *Times*.

So early as August 29, 1914, Meldola realised the difficulties ahead, and wrote to a colleague: "I think of preparing a general plan of campaign for recovering British chemical industries lost through German competition." On September 22 he presided at a joint meeting of the Councils of the Institute of Chemistry and the Society of Public Analysts, at which special committees, one of them dealing with glass, porcelain, and filter-paper, were appointed. He was chairman of the latter committee and also of the special Glass Research Committee appointed on October 30 by the Institute of Chemistry. He presided at nearly all the numerous meetings of this committee, attending one only three days before he died, " working to the very last in his great desire to advance the interests of his country and of chemical science." I quote the words of his colleague, Prof. E. G. Coker, in the brief reminiscences of Meldola published by Williams and Norgate in 1916.

The letter which appeared in the *Times* is sufficient proof that these facts are not known as they should be or have passed out of mind. Nevertheless, there must be many who remember the debt that is owing to Raphael Meldola, and they surely will " see to it that his name be not forgotten."

Edward B. Poulton.

Oxford, February 25.

Names for Companion Stars.

Although it has not been customary to give specific names to the dark or inconspicuous companions of bright stars, there are one or two such bodies of so much interest and importance, and likely to be so constantly referred to in the science of the future, that perhaps exceptions might be made in their case. I write, therefore, to ask whether an outsider in astronomy may modestly make a suggestion for astronomers to consider, and to reject if they do not approve.

The companion of Sirius is so extraordinary a body, and the detection of its specific properties is the outcome of such brilliant work, that I suggest that the name Eddington might be applied to it. Presumably less is known about the companion of Algol—the first spectroscopic binary—and possibly, as it seems dark, it scarcely deserves a name; but the name of its discoverer, Vogel, might perhaps be attached to that.

These suggestions may be rather presumptuous; but no harm seems likely to be done by their publication.

The Nature of Active Nitrogen.

I have not been able to follow in detail the recent discussion on the nature of active nitrogen, being closely occupied with other problems. It seems worth while, however, to direct attention to a part of my early work which seems to have dropped out of notice, but is, I believe, worthy of attention (Strutt, *Proc. Roy. Soc.*, A, vol. 86, pp. 264-267, 1911). It is there shown that the luminosity of active nitrogen can, as it were, be squeezed out of it by compression, the luminous emission of the α (1st positive) group of bands, and, perhaps the other series also, but this was not investigated, being immensely enhanced by compression. When the old volume is restored, it is found that the capacity to produce the glow is exhausted, though, apart from the compression, it would have lasted much longer.

The experiment was regarded at the time as proving that the action is bi-molecular, and I think is at least as telling as any other evidence pointing in the same direction.

Rayleigh.

Terling Place, Chelmsford,
February 27.

As the result of investigations which have been proceeding for some time, the writer, in collaboration with Dr. E. K. Rideal, has been able to show by three independent methods that the heat of formation of active nitrogen is about – 43,000 cal per gm. molecule.

This is in agreement with the value suggested by Strutt in 1911, and since it is known that the heat of dissociation of the nitrogen molecule is most probably of the order of – 300,000 cal. per gm. molecule, the hypothesis that active nitrogen is atomic cannot well be substantiated. Rather would it appear that 'active' nitrogen represents a metastable molecule at not a very high energy level.

A full account of the investigations will shortly be published.

A Mistaken Attribution in South American Linguistics.

With reference to the note under the above title in Nature of February 20, p. 283, it may be of some interest to point out that the Arda in question no doubt refers to Ardra, Arder, or Allada, formerly one of the greatest towns on the Dahomian coast, which was conquered by King Agaja of Dahomey in 1724. The inhabitants speak a variety of Ewe, very similar to the ordinary Popo.

There was a considerable trade in slaves between Dahomey and the Brazils, and it is conceivable that descendants of Ardra slaves penetrated to the part of Amazonia mentioned in the text.

The Species Problem and Evolution.[1]

By O. W. RICHARDS and G. C. ROBSON.

II.

CORRELATION.

THE mutual relation and interaction of the various characters by which species are distinguished from each other is very imperfectly understood at present. On one hand, all the characters distinguishing a species may, or may not, form an integrated system. On the other hand, certain characters may be correlated with one another to some extent. The possibility that the characters of different species may form integrated systems is at present very uncertain. The only evidence in support of this view is derived from certain inter-specific crosses in which the parental characters segregate *en bloc*; and further investigation of this subject is urgently needed.

Whenever two characters always seem to occur together they may be related as cause and effect, or both may be due to the same cause. When this is the case, and when the effect cannot be traced clearly to the cause, such a relation will be called merely correlation. Two characters may be also correlated by genetical means, either being linked or by a varying number of individuals of a population being homozygous for both of them. These types of correlation will rarely be absolute. The former must be of some importance, but cannot be a universal explanation of correlation, since it will not often happen that all the characters that are found to be correlated in a species are due to genes situated in the same chromosome. The latter means of correlation is certainly of wide importance; perhaps two characters which are highly correlated in a species, but segregate out when an inter-specific cross is made, are always correlated in this way. A special agency must obviously be invoked to account for the existence of a character in the homozygous condition in most of the individuals of the species when it arose originally in only a few.

ISOLATION.

In this section are to be considered causes of isolation other than topographical barriers. A number of explanations have been put forward to explain failure to interbreed on the part of species which seem to have every opportunity of crossing. Thus it has been supposed that differences in the copulatory organs might produce a mechanical barrier between species so differing. Such mechanical isolation, however, can not often be effective. In the first place, when such differences in the copulatory organs do occur, they are often restricted to the male and, when comparable differences occur in the female as well, no coadaption of the organs of the two sexes has been shown (Boulangé, 1924). Furthermore, species which differ in their genitalia have been crossed without mechanical difficulty.

There are many cases known in which closely allied forms living together with ample opportunities for interbreeding rarely cross in Nature. The cause of this disinclination to interbreed ('selective mating') can rarely be assigned to known differences between them. There are certain factors which may be important in particular cases, for example, differences in scent and mating-behaviour. Selective mating may even occur within a species; for example, Crozier (1918) has shown that in Chromodoris the pairs that interbreed tend to be of the same size and that large specimens rarely mate with small. Where differences in habitat and seasonal occurrence exist, they more obviously produce some degree of isolation; but it is not often that either of these alone would be completely effective. As we have seen, none of these modes are universal causes of isolation when acting alone; but in any case in which several were involved at the same time, isolation might be nearly complete. When interbreeding is not stopped by any of these means, sterility may yet make it ineffective. In motile animals, in which alone selective mating can occur, sterility is not necessarily a primary cause of isolation. It has been already seen that it by no means always precedes or even accompanies the early stages of structural divergence. In these forms probably some kind of selective mating is most often the cause of isolation, and sterility is due to later divergence.

In forms in which the male fertilising element is carried to the ovum by external agencies (for example, in plants and sessile animals, etc.), isolation can only be produced by differences in breeding-season or by sterility. Although in some species isolation is produced by the former means, it is probably not in the majority, and the latter must be more or less sterile when crossed. In the case of plants there are some genera in which the species concept breaks down owing to the absence of marked sterility or any other means of isolation among the members.

EVOLUTION.

The initial stages of evolutionary divergence involve three processes: (1) the occurrence of variations, (2) the spread of new variations in a species, and (3) the break-up of a species into different populations.

1. The origin of heritable variation is still very obscure, and in particular there is as yet no clue to the origin of those changes in habits which must have played so important a part in evolution. There may be said to be three main views on this subject: that heritable variation is the result of automatic change in the germinal material, that it is due to change produced in the germ cells by external causes, and that it is the effect of change produced by such causes in the soma and transferred to the germ cells. In practice it will be difficult to distinguish between the second and third of these.

The experiments which have been conducted to elucidate this problem are by now numerous; but in spite of them the problem is still unsolved. For one reason or another, the results which are claimed to prove that the effects of the environment can be transferred from the soma to the germ cells have had to be rejected or are still *sub judice*. Each of these experiments is of course entitled to separate consideration, and some are of greater merit as experiments than others. With justice, however, it must be said that they do not as yet collectively form a convincing body of evidence.[1]

---

[1] Continued from p. 347

Of the direct modification of the germ cells as a factor in evolution we have likewise no decisive proof, though there is some circumstantial evidence in favour of this possibility. The means by which the germ cells have been experimentally modified rarely seem, however, to bear any relation to the natural environment of living organisms. It is a fair criticism to suggest that very few of the experiments designed to elucidate this problem reproduce those environmental circumstances in which evolutionary change must be assumed to have taken place.

The action of the environment may perhaps be seen in the following examples, in which, however, it is difficult to say whether the effects have been on the germ cells and soma or on the germ cells alone. These examples fall into two classes. On one hand, the species of a genus may be so distributed that they occur at different points in the gradient of some environmental factor (for example, temperature, humidity) Some special variation in the species (for example, hair-length) may be correlated with the change in the environment. This variation may be seen both within a species in different parts of its range and by the comparison of species the ranges of which include different parts of a gradient. When a character shows a correlation with changes in an environmental gradient, it is of course difficult to prove that the changes in the character are neither phenotypic nor adaptive, though in particular cases this may be most unlikely. On the other hand, there are a number of cases in which in allied species identical morphological varieties are of two kinds—heritable and non-heritable. For example, Crow (1924) has given examples in the Algæ of characters which are only developed in special environmental conditions in one species, but appear to be genetically fixed in others. Though these examples prove nothing as yet, they suggest a useful line of inquiry into the causes of variation.

In order to explain certain special types of evolutionary phenomena, some authors have recourse to two theories which are sometimes confused—the principles of Orthogenesis and of Momentum and 'Programme Evolution' (Eimer, W. Lang, Dendy, Osborn). The former principle expresses the idea that in allied forms, for an indefinite time after divergence, there is an innate capacity to produce the same type of variant. If this were true in a wide sense (which is not yet shown) it would be wrong to assume that species could respond to environmental change by variations in all directions. The terms Momentum and Programme Evolution, though not applied to identical phenomena, seem to have very much the same implication. One refers to the development in certain groups of monstrous or over-complicated structures; the other is applied to 'determinate' evolutionary series, which are accomplished without any apparent reference to Natural Selection or any other principle. At present, however, these three terms are labels for types of evolutionary phenomena which are of obscure causation and uncertain frequency.

It is perhaps necessary to point out that possibly new forms may arise by fresh combinations of pre-existing characters. There is a certain body of evidence that has been thought to show that new species may arise as a result of crossing. This evidence and the corresponding cytological data relate almost exclusively to plants. The rôle of this process in evolution is as yet very uncertain, and, if it is operative at all, its effect is probably limited.

2. The process of divergence by which species arise consists either of the consecutive differentiation of one character after another, or perhaps in the change of a large set of characters *en bloc*. For the occurrence of the latter there is only a little evidence which has been mentioned previously. Variations as a rule must arise in a few individuals, except where the environment has some identical effect on all the members of the species; so that as a rule the addition of new characters implies the spread of variations in the population. This is usually supposed to take place mainly by the action of Natural Selection, which ultimately requires that species must differ in adaptive characters.

In the first place, it is practically impossible to show that a character is not of value to an organism without an exhaustive knowledge of the life history and physiology of the latter. On the other hand, the adaptive value of a structure must not be presumed in default of evidence to the contrary. A character can only be called adaptive (*a*) if it is useful, (*b*) if its possession does not entail a counterbalancing disadvantage. In the following discussion it is merely the utility of characters which will be considered.

A character which is not directly useful may be correlated with a useful one, as Darwin suggested. It would be a very difficult thing, however, to give an example of this in which the character is specific. No doubt such cases do occur, and perhaps even frequently; but they cannot be assumed to play an important part in evolution until direct evidence of their frequency is forthcoming.

The direct utility of the characters previously described as specific may now be considered.

(*a*) *Structural.*—There is not very much satisfactory evidence of the utility of the differences between closely allied species. There are some observations (summarised by Pearl (1917)) which suggest that certain small structural characters may be of selective value, though Pearl points out that other investigations of this sort yield no such result. It is also the case that, when allied species differ in their mode of life, their structural differences do not in general seem to be connected with such differences in the habits (but cf. Regan, 1925, p. 5).

(*b*) *Physiological.*—The evidence here is very unsatisfactory; but such physiological differences between allied species as are known are not yet shown to be of survival value.

(*c*) *Reproduction.*—It is difficult to see any sense in which the differences in sterility between crosses can be adaptive. As regards the differences in secondary sexual characters, some seem to be quite unconnected with mating, and many of them are very unlikely to be directly useful. Any character which plays a part in mating may, however, have been influenced by some form of sexual selection.

---

[1] Since this article was written, an important paper by Messrs. J. W. Heslop Harrison and F. C. Garrett has appeared (*Proc. Roy. Soc.* B, 99, Feb. 1926, p. 241) on the inheritance in Lepidoptera of melanism induced by the presence of lead and manganese in their diet. These results seem in general to be above criticism, but their precise significance cannot be discussed in this brief notice.

(*d*) *Habitat and Food.*—When allied species differ in habitat and food it has been assumed that they are structurally or physiologically adapted to such divergences; yet it is not only in many cases quite unproved that such adaptations occur, but even if they do occur it is very uncertain which type of difference was primary. The rôle of Natural Selection in producing such differences is very dubious

(*e*) *Miscellaneous Differences.*—It is difficult to find any case in which survival value may be attributed to the differences in behaviour which come under this heading.

It thus seems that the direct utility of specific characters has rarely been proved and is at any rate unlikely to be common. Furthermore, since the correlation of structure, etc., with other characters shown to be useful does not at present rest on many well-proved examples, it cannot yet be assumed that most specific characters are indirectly useful. Thus the rôle of Natural Selection in the production of closely allied species, so far as it is known at present, seems to be limited. This statement is not to be taken as a wholesale denial of the power of Natural Selection. The latter is not in question when structural differences of a size likely to effect survival are involved. It is only the capacity of selection to use on a large scale the small differences between closely allied species that is unproved.

Recently another process which occurs in Nature has been suggested as a possible cause of the spread of characters whether adaptive or not (Elton 1924). Many animals are subjected to severe fluctuation in numbers through epidemics, bad weather, etc., and this has two possible effects. The usual result would be that the small number of individuals left over after, for example, an epidemic, would not include many of the uncommon variations, and the number of different variants in the population would be continually limited. After a minimum there is of course room for many more individuals than are actually found, so that during the subsequent multiplication there may be little or no competition. If an uncommon variant survived by accident, or if an unusually low minimum did not leave a random sample of survivors, then in the course of multiplication the character of the population would be changed. At present this seems to be the most likely means by which an entirely unadaptive character could spread.

3. If variations arise in only a few individuals at a time, they will not often be spread quickly to all the members of a species, so that if samples of a widely distributed species be taken from different parts of its range they are likely to differ in the collection of characters which distinguish them. Such difference will be further accentuated if the area occupied is broken up by topographical barriers which may cause isolation. This, however, to be permanent must be grounded in some of the other causes referred to above (for example, selective mating). Some animals live in colonies, such as certain land snails (Cepea) and moths (Zygaena). Of these the former have a limited power of dispersal, while the latter, in spite of their power of flight, tend to keep to their own colonies. Adjacent colonies which are not separated by impassable barriers may differ in the same way as do the geographical races of widely distributed species. Thus two forms living at separate points in the range of a species may differ in a number of characters which, acting in conjunction, may cause isolation, while neither of them would differ from its next-door neighbour enough to produce this result. It has been suggested that most widely distributed forms constitute such "syngamic chains" (Poulton). Anything which breaks this chain would isolate two groups which sooner or later might become two distinct species. The origin of variation in habits within a species is at present not yet well enough known to enable us to make further generalisation about the methods by which isolation is produced.

Conclusion.

There are many characters (structural, physiological, etc.) by which species may be distinguished, but differentiation does not take place to the same extent in all of them, and sometimes, as criteria, they are at variance with each other. As no standard can be proposed by which species may be distinguished from varieties, there is no absolute criterion of species. Failure to interbreed is perhaps the nearest approximation to such a criterion, and it is also possible that a special type of sterility may be revealed which might provide a more definite limit than that indicated by structure. The nature of the various grades of sterility, however, requires a more complete analysis. At present the incidence of specificity is very imperfectly understood, especially in physiological characters. Even in structural divergence it is not yet known why in each group of animals certain organs tend to show the effects of divergence sooner than others.

Causes which in theory should spread new characters through a population are known; but much more evidence is required as to their actual operation and as to the extent and nature of the correlation that has been observed between specific characters. It is very unlikely that divergence at its earliest stages is promoted to an important extent by Natural Selection. In Nature, species are more or less broken up by causes leading to permanent isolation. These causes may be numerous; but at present we know very little as to the *primary* cause in any particular case—whether, for example, divergence in habit precedes that of structure or vice versa, and whether sterility precedes or follows structural divergence. Finally, there is very little exact knowledge as to the physiological differences which must occur between forms having different habits.

The Electrical State of the Upper Atmosphere.

THE meeting of the Royal Society on March 4 was devoted to a general discussion on the subject of "The Electrical State of the Upper Atmosphere," at which a number of prominent physicists interested in this subject had been invited to take part. The large attendance at the meeting showed the importance of the subject in the scientific world at the present time; and it was evident that a very useful purpose was being served in directing the attention of the meteorological and atmospheric physicists to the insistent demands made by modern wireless research for an upper ionised stratum in the atmosphere which is capable of deflecting wireless waves and returning them to the earth's surface.

In opening the discussion, the president of the Royal Society, Sir Ernest Rutherford, outlined the three possible methods of investigating the upper atmosphere. Above the limits of direct observation, the pressure and temperature are to some extent calculable, while observations on meteors provide experimental information. The highly penetrating radiation recently investigated by Millikan was found to increase in intensity upwards from the earth's surface, and the suggestion was made that this radiation might possibly originate in thunderstorms. It was pointed out that in order to obtain a permanently ionised layer it is not necessary to assume a very strong ionising agent; since, owing to the slow rate of recombination at the higher levels, a small rate of production of ions may result in a very large permanent ionisation

With the aid of a carefully prepared chart, Prof. Sydney Chapman, of the Imperial College of Science and Technology, then summarised our present knowledge of the physical constants of the atmosphere. By means of self-registering instruments carried in sounding balloons, direct observations have been made at heights up to 30 km. The absolute temperature of the atmosphere decreases from 285° at the earth's surface to 220° at a height of 10 km., which is the upper limit of the troposphere. Above this the temperature remains constant up to a height of 60 km., where it begins to increase again to a value approaching 300° for a height of 100 km. At this height the pressure and density of the air have values which are about 10^{-5} of those at the ground level, while the mean free path of the molecules increases from 10^{-5} at the earth's surface to 3 cm at 100 km. height. The gaseous constituents of the atmosphere are thoroughly mixed as the result of winds in the lower regions, but they become separated at the higher levels with nitrogen as the main constituent The existence of aurora at heights of from 90 km. upwards appears to require the lifting of gases from the lower regions. Attention was further directed to the comparatively high conductivity which the ionised layer is required to possess in order to explain the phenomena of terrestrial magnetism

Mr. C T. R. Wilson referred to recently published data on thunderstorm distribution, from which it has been deduced that about 1800 thunderstorms are in continual progress over the earth's surface, accompanied by lightning flashes at an average rate of one hundred per second. Combining these results with the experimental measurements of the quantity of electricity in each lightning flash, it was shown that these thunderstorms represent an energy supply having the enormous value of 10^{11} watts, which, however, is only 10^{-4} of the energy received by the earth from the sun in the form of heat. It was suggested that electrons moving in electric fields with strengths of the order of 10,000 volts per cm. in the neighbourhood of lightning flashes, may be responsible for a very penetrating form of radiation in the atmosphere. In a later portion of the discussion Mr. Dobson described results obtained in observations on the disappearance of meteors and showed that this leads to increased values for the temperature and pressure of the atmosphere at heights of the order of 100 km.

The radio aspect of the discussion was opened by Sir Henry Jackson, who emphasised the long-felt need of an adequate explanation of long-distance wireless signalling, of the variations in signal intensity, and of the more recently observed variations in apparent directions of arrival of wireless waves at a receiving station. He stated that during the last few years an enormous amount of experimental data on these points has been obtained by a group of investigators associated with the Radio Research Board and that the experimental facts are now well established. All this work indicates the necessity for a layer in the upper regions of the earth's atmosphere which is capable of deflecting waves reaching it in such a manner as to return them to the earth's surface. A brief account was also given of some recent experiments carried out on a wave-length of 12 metres in which a ship transmitter was employed. As the ship proceeded away from the receiving station the signals disappeared for a range of transmission of about 100 miles. This was presumably due to the high attenuation of such waves in travelling over the earth's surface, although accurate knowledge on this point is still lacking. As the ship proceeded on its course no signals were received until the distance was increased to 1100 miles, beyond which the signals again disappeared. At 3000 miles and again at 6000 miles the signals were very clearly heard, although they were inaudible at intermediate ranges. Such results as these demand for their explanation an ionised layer which will permit the passage of wireless waves with a very small attenuation and will arrange for waves to be returned to the earth at certain places only.

Prof. E. V. Appleton indicated the desirability of investigating the wireless phenomena at comparatively short distances, and then described two sets of experiments, carried out with the assistance of Mr. M. A. F. Barnett, which provide proof of the reception of downcoming wireless waves at the earth's surface. The first of these demonstrated the interference between two sets of waves from the same transmitting station, one set having travelled along the earth's surface and the other set via the upper regions of the earth's atmosphere. The second experiment was based on the fact that, for an electromagnetic wave arriving at the surface of a conductor, the resultant horizontal magnetic force is greater than that of the vertical electric force, and by measuring the ratio of these forces the angle of incidence of the waves can be calculated. Attention was directed to the importance of the earth's magnetic field on the operation of the ionised layer, and also to the fact that, from observations on very short wave-lengths, information is obtainable as to the density of electrons required in this layer.

The next contribution to the discussion was made by Dr. R. L. Smith-Rose and Mr. R. H. Barfield, who gave a brief account of some of their recent experimental measurements on wireless waves received from the upper atmosphere. By means of careful measurements of the directions of both the electric and magnetic forces at the earth's surface due to wireless waves from a distant transmitting station, it was shown that, at times in the neighbourhood of sunset and in the hours of darkness, some of the received waves were travelling in a downward direction, evidently the result of deflexion from the upper atmosphere. Several methods of measuring the angle of incidence and relative intensities of such waves have been developed and give consistent results. In an example given in the paper, the angles of incidence varied from 13° to 34°, and the latter value is shown to correspond to a height of deflecting layer of about 88 km, which is in good agreement with the results of other investigators. The intensity of such downcoming waves is of the same order as the direct wave along the earth's surface which is received simultaneously, and the combination of the two sets of waves is responsible for the variations in signal intensity in the readings of a direction-finder which were observed during the experiments. The need for further investigation and the lines of proposed future experiments were mentioned by these speakers.

In concluding the radio side of the discussion, Prof. W. H. Eccles reminded the audience that the observed effects might vary very much over the enormous range of wave-lengths which is now being used in practical wireless communications. The diffraction of the waves around the curvature of the earth would be appreciably different with wave-lengths of, say, 20 and 20,000 metres, and it is also possible that the shorter of these waves may be returned to earth at a comparatively low height, about 30 km, in the atmosphere. The speaker directed attention to some lacunæ in the Larmor theory of the propagation of waves, and emphasised the need of further experiments directed towards the elucidation of some points which are at present somewhat obscure.

Among the speakers who took part in the later portion of the discussion, Dr. G. C. Simpson stated that Britain now leads the world in the matter of knowledge and research on the science of the upper atmosphere.

Transatlantic Radio Telephony.

ON Sunday, March 7, the General Post Office gave representatives of the Press an opportunity of taking part in the engineering tests, made in the ordinary course, by the technical staffs of the General Post Office and the American Telegraph and Telephone Company. Mr. Shaughnessy, the engineer in charge, gave an interesting résumé of what has already been done. He also described the route that is travelled by the voice signals and detailed some of the many difficulties that will have to be overcome before two-way telephony between London and New York can be established on a commercial basis. So far back as 1914 the engineers of the Bell system in the United States succeeded in establishing one-way communication between Arlington and Panama, San Francisco, Honolulu and Paris successively. Three years ago similar experiments between London and New York proved that it was highly probable that a limited two-way service could be established.

In England, the circuit ends at the London Trunk Exchange of the British Post Office. In the United States it is terminated at the headquarters of the American Telegraph and Telephone Company at 24 Walker Street, New York City. In speaking from London, the signals are carried by underground telephone wires through two repeater stations direct into the microphone of the Post Office Radio sending station at Rugby, where the aerial used is carried by five lattice masts each 820 ft high and a quarter of a mile apart. The radio signals then go a distance of 2900 miles to the receiving station at Houlton, Maine From there they traverse a distance of 600 miles through two repeater stations to New York.

In transmitting from New York the speech is carried a distance of 70 miles to the sending station of the Radio Corporation at Rock Point, Long Island. From there it is transmitted by radio a distance of 3300 miles to the Post Office receiving station at Wroughton, near Swindon. From this point it is carried over a telephone circuit to London, a distance of 90 miles

The wave-length utilised in England is 5770 metres and in the United States 5260 metres The power used at each end is about 200 kilowatts, but owing to improvements in the method of radio transmission adopted, the ordinary broadcasting telephony station would have to employ about double this power to attain the same efficiency.

Arrangements were made by means of which some twenty press representatives in London had two-way conversations with their American confrères. These conversations could be overheard by all those present. The speech was remarkably clear, being quite equal to that heard in ordinary telephony. It was stated that the atmospheric conditions were favourable. Very little disturbance was produced by Morse or atmospherics. The difference between the voices of the speakers was clearly recognisable. This was the first occasion on which group conversations by the public were held between London and New York.

The Post Office engineers are to be congratulated on the many difficulties they have overcome, particularly in balancing the land telegraph lines in order to get two-way transmission. We are still, however, a long way from commercial telephony across the Atlantic. Doubtless it will come in the future. We wish the engineers every success in their strenuous endeavours.

Obituary.

Prof. A. R. Cushny, F.R.S.

The sudden death of Prof. A. R. Cushny, professor of materia medica and pharmacology, University of Edinburgh, at the early age of sixty years, is a severe loss to medical science and to pharmacology in particular, for he was one of the chief pioneers of this science. The outstanding events in his career are as follows:—He was educated at the University of Aberdeen, and then studied on the Continent, and from 1892–1893 was assistant to Schmiedeberg at Strasbourg. In 1893 he went to the University of Michigan as professor of pharmacology, and in 1905 returned to England to take the chair of pharmacology at University College, London. In 1918 he went to Edinburgh to take up the post he held until his death.

Cushny made many important contributions to our knowledge of pharmacology and physiology, but his name is associated particularly with his investigations upon the mode of action of digitalis on the heart, and upon the secretion of urine. Whilst at Michigan, he carried out a series of researches of fundamental importance which established the mode of action of digitalis on the mammalian heart; and later in London, in association with his friend the late Sir James Mackenzie, he applied the knowledge gained in these researches to the study of the therapeutic action of digitalis. In 1925 he summarised our present knowledge of this subject in a monograph on digitalis and its allies.

Cushny carried out numerous important researches on the mode of secretion of the urine, and in 1917 he published a monograph, in which he advanced the first coherent theory regarding the secretion of urine which accords at all with modern ideas of physical chemistry.

It is as one of the chief pioneers and founders of the science of pharmacology, however, that Cushny will be especially remembered. In 1899 he produced the first edition of his well known "Textbook of Pharmacology and Therapeutics," which was the first systematic textbook on this subject to be published in English He had a very remarkable power of shrewd and balanced judgment, and this was based not only on an exceptionally wide knowledge of pharmacological literature, but also on a personal knowledge of all the leading pharmacologists in the world. This combination of knowledge and judgment gave his textbook an unrivalled authority. His whole influence was thrown towards making pharmacology an exact science, and he admitted no tradition of therapeutics as a fact unless it was supported by definite evidence. For these reasons, the work has had a profound influence on the development of pharmacology in Great Britain and has greatly assisted the growth of the subject as an exact science.

Cushny's personality made him an exceptionally fine teacher and inspirer of research. His kindness and patience were inexhaustible, but his wide knowledge and shrewd judgment made him the natural enemy of anything like slack or inaccurate work. He founded the school of pharmacology at Michigan and made it an important centre of research, and repeated this performance in London. Finally, when he went to Edinburgh he found research work in Pharmacology at a low ebb and in a few years established a strong school. Cushny was the senior pharmacologist in Britain, and his wide experience and knowledge, his strong but kindly personality, and his great powers of judgment, made him the natural leader of his scientific colleagues, and also one whose advice was greatly valued on matters scientific, academic, and personal.

In addition to his scientific and academic activities, Cushny also served on numerous commissions and other public bodies, notably on the Chemical Warfare Committee, the Central Control Board (Liquor Traffic) and the Council of the Royal Society.

Cushny was a great pioneer and leader, and his untimely death is an irreplaceable loss to the medical sciences. Those who, like the writer, worked under him as assistant, have double cause to mourn the loss of a great teacher and kindly friend. His circle of friends was world-wide, and the sympathy of all will be extended to his widow and daughter in their sudden bereavement.

Prof. D. S. Capper.

Prof. David Sing Capper, who died from heart failure following acute rheumatism on February 12 at his home in Golders Green, was for twenty years professor of engineering in the University of London, King's College. He retired from this position in 1921 to devote himself to the commercial side of engineering. At the time of his death—he was only sixty-one years of age—he held the position of director in the Haulage Improvement and Constructions, Ltd., a company interested in the development of mechanical road transport.

Prof. Capper's early training, like that of most educated Scotsmen of his time, was of a wide and varied nature with a classical bias. After taking his degree at Edinburgh, he adopted the engineering profession and studied for some time at University College, London, under Sir Alexander Kennedy. His practical experience was obtained first as a pupil with Messrs. R. and W. Hawthorns of Leith, and later with Messrs. Humphrys, Tennant and Co, of Deptford, where for two years he acted as assistant to Mr. R. Humphrys. He took an energetic interest in the proceedings of the principal engineering societies, and was a member of the Institution of Civil Engineers, the Institution of Mechanical Engineers, and the Junior Institution of Engineers.

Prof. Capper was appointed professor of engineering at King's College, Strand, in 1890, and in 1905 he published, in the First Report of the Steam Engine Research Committee, the results of his long and important research on valve leakage carried out under the auspices of the Institution of Mechanical Engineers. The same year he became a member of the Senate of the University, and so many-sided were his manifold educational activities that at different times he had the distinction of being a governor of Sir Roger Cholmeley's School, a member of the governing body of the Imperial College of Science and Technology, and a member of the delegacy of King's College. He gave of his best in such services, where his long experience, persuasive manner, an almost uncanny quickness in summing up the gist of a resolution, and an unfailing sense of the feelings of a meeting, made his presence a great asset.

Consistent with his leaning towards the practical side of his profession, Prof. Capper carried on a consulting practice for many years in addition to his other duties. Incidentally he was one of the pioneers of the 'Sandwich' system of training for engineers, wherein a student gained works experience with some well-known engineering firm in tandem with his college degree course each year for four years, instead of the usual three at college only.

When in 1908 Lord Haldane introduced his plans for the formation of Officers Training Corps at the various universities, Prof. Capper threw himself into the scheme with whole-hearted enthusiasm, and with characteristic zeal undertook the difficult task of commanding the University of London contingent. Later, with a stimulating sportsmanship, he passed all the examinations, and through every stage in the training curriculum of a territorial officer, from the barrack square at Chelsea to the School of Musketry at Hythe. In August 1914 he took command of a training camp for two hundred young officers at Headley, and eventually commanded various training schools for officers. He transferred to the 2/5th Royal Warwicks in 1916 as temporary major, readily sacrificing his rank of lieut.-colonel in his keenness to serve overseas. Then at the age of fifty-one years this university professor went out into the trenches as second in command of an infantry battalion; an example of patriotism and pluck which is worthy of record. Early in 1917 he was invalided home on account of heart trouble and transferred his energies to the Ministry of Food, where he assisted in a research on food preservation until the end of the War, when he returned to his duties at King's College.

O. S. S.

WE much regret to record the death, on February 26, of Mr. Henry Hatfield, I.S.O., barrister-at-law, for more than thirty years Chief Examiner at the Patent Office. Born at Stockport in 1854, and educated at Owens College, Manchester, and the Royal College of Science, Dublin, Mr. Hatfield intended to enter for the Geological Survey. He went to the Patent Office instead, however, in 1878, becoming Chief Examiner in 1888, and later was authorised to act for the Comptroller-General. During his regime many changes in patent procedure were inaugurated, notably the modern methods of 'search' by a scientific staff. To the general scientific public, his work in connexion with the founding of the Patent Office Library, which has now become one of the best scientific libraries in Great Britain, will be better known.

News and Views.

A LARGE company of the Royal College of Science Association and others assembled at the Imperial College Union, South Kensington, on Friday last, March 5, on the occasion of a complimentary dinner to Sir John Farmer, professor of botany in the College, upon whom the honour of knighthood was conferred by the King at the beginning of this year. Sir John Farmer is the senior professor of the Royal College of Science, and when the Imperial College was instituted by Royal Charter in 1907 for the purpose of giving the highest specialised instruction, and providing the fullest equipment for the most advanced training and research in various branches of science, especially in its application to industry, doubt was expressed as to whether botany could appropriately be brought within the contemplated scheme. Fortunately, its economic significance was realised, with the result that the department devoted to instruction and research in this branch of science has become of the greatest value in the development of the plant resources of the British Empire. Students trained by Sir John Farmer now hold responsible posts in educational institutions, agricultural stations, and great plantations throughout the Empire, and when he visited Trinidad a year or so ago, as many as five in that single place were at the port to welcome him. Mr. Herbert Wright, who proposed the toast of the guest of the evening, testified as an old student to the wide and stimulating influence of Sir John Farmer's work. To have established a school of pure and applied botany which has contributed so much to scientific progress and practical service is a great achievement, and we cordially associate ourselves with Sir John Farmer's colleagues and students in congratulating him upon it and the recognition of his work represented by the honour recently conferred upon him.

PROF. ARNOLD SOMMERFELD, who on Wednesday, March 3, delivered the first of a course of three lectures on "Atomistic Physics" at the Imperial College of Science and Technology, under the auspices of the University of London, is one of Germany's leading mathematical physicists. He is now professor of physics at the University of Munich, where he is a colleague of Prof. Wien, who visited Great Britain last year Prof. Sommerfeld was born in 1868, and during the early years of his career published many papers on various branches of theoretical physics and pure mathematics. He is known chiefly, however, on account of his more recent work in developing the application of the quantum theory to the problem of the spectra of the elements, initiated by Bohr. Independently of Wilson he showed that by a generalisation of Bohr's original theory of the hydrogen atom to include the possibility of elliptic orbits, and the introduction of the relativistic change of mass with velocity into the equations of electronic motion, the existence of a 'fine-structure' of the series lines of hydrogen and ionised helium might be expected—a prediction which was brilliantly verified in the case of ionised helium by Paschen. Later he introduced into the discussion of spectral term-relationships the idea of 'inner quantum numbers,' which, since the discovery of multiplets by Catalan, has received a very wide application His book, "Atombau und

Spektrallinien," first published in 1920, has already passed through four editions, and is recognised as the standard work on the subject. It has been described as 'the twentieth century bible.' An English translation of the third edition, under the title "Atomic Structure and Spectral Lines," appeared in 1924.

A DEPUTATION from the Universities of Cambridge and Edinburgh was recently received by the Colonial Secretary with reference to the inauguration of an Imperial Forest Research Institute at the University of Oxford, combined with a fourth year's course in forestry. This project had been recommended by the Empire Forestry Conference which met in London in 1920. Few members of that Conference had full knowledge of the great progress made in forestry education at Cambridge and Edinburgh as the result of a recommendation of the Commission appointed in 1908 by the India Office after the closure of Cooper's Hill. That Commission invited these universities to inaugurate and equip schools of forestry, pointing out that competition would be to the benefit of forestry. At both universities forestry education up to a fourth year's post-graduate honours course was instituted Only the Colonial Office and the Forestry Commission took up the recommendations of 1920 and provided the funds with which the Institute and fourth year's work were started at Oxford, provisionally for five years, in October 1924. In selecting candidates for employment, from men with a degree or diploma in forestry, these two departments make an allowance to the chosen probationers and insist on their proceeding to Oxford to take the fourth year's course. The deputation pointed out the hardship thus incurred by men having to change their universities and, in the case of Edinburgh, to incur a far greater expense. In the opinion of the delegation, the innovation would result in a decrease in a good type of man coming forward to take forestry as a career.

A PAPER on the applications of electricity to agriculture by Mr. Borlase Matthews was read and discussed at the Institution of Electrical Engineers on March 4. He succeeded in proving many useful and convenient applications of electricity in connexion with farming. In his opinion, when a quarter of the area near a transmission line is arable land, the supply will prove profitable to the electric company. A specification is given of the author's electric tractor suitable for small farms. It is designed for ploughing, general haulage, and many other field operations. When carrying out field work, the machine takes its supply of current from an overhead wire and a cable laid on the ground. It has a 'half creeper' track so that it can go over rough ground. It also has a storage battery, so that it can proceed from field to field as well as haul loads on the public road It seems possible that the plough may be replaced by the rotary tiller, which has many points in its favour. This machine is excellently adapted for an electric drive, and the latest type of instrument buries the weeds and leaves, a result desired by most farmers. From the financial point of view, however, a strong case was not made out. Ploughing only takes place over a limited period of the year, and so it does not offer that uniform load desired by electric companies. Mr. Matthews' electric tractor, however, offers possibilities which should be further explored.

SIR HENRY MAYBURY, Director-General of Roads Department, Ministry of Transport, in his discourse on "London Traffic" at the Royal Institution on Friday evening, March 5, stated that the problem of the transport facilities of the great Metropolis cannot be solved unless it be approached on scientific lines. In 1903 a Royal Commission was appointed to inquire into the question, and made recommendations for improvements to which effect was never given. Another Royal Commission was appointed in 1921, and the outcome of its recommendations was the passing of the London Traffic Act in 1924, and the appointment, under the Minister of Transport, of the London and Home Counties Traffic Advisory Committee. This Committee has made a thorough investigation of the various tramways and omnibus routes, and is required to supervise an area within a circle extending about 25 miles from Charing Cross. The engineering staff of the Committee has given much attention to the bridge question in the traffic area, and is making a report thereon. The results of the Committee's recommendation have been so far successful in the adoption of the gyratory or continuous working arrangement as now in operation at the end of Parliament Street, Bridge Street, and near the Victoria Memorial; and schemes of identical character have been approved for Trafalgar Square and Hyde Park Corner. By utilising many of the existing subsidiary roads, which may be made continuous and through routes, and by the use of effective direction signs by day and night, it is believed that with much advantage a large amount of traffic can be deflected. The Committee is proceeding with negotiations with the various local authorities, in order to find a satisfactory solution to the vast problem of London traffic, which is of so much importance to the comfort, health, and general welfare of the citizens of London.

SEVERAL valuable papers on power-plant design and operation were read and discussed at the December meeting of the American Society of Mechanical Engineers held in New York. These papers are of special interest in Great Britain at the present time. In the United States cheap overhead lines are permitted, and this leads to the building of super-power stations. As the cost of labour is high, this also accentuates the economies effected by their use. Mr. C. W. E. Clarke describes the rapid advances made by the Colfax station of the Duquesne Light Company. It began to operate in 1920 with a turbo-alternator generating 60,000 kilowatts. The steam pressure used was 275 lb. per square inch and its temperature was 600° F. In 1923 it was decided to use pulverised fuel and to raise the steam temperature to 650° F., preheated air being supplied to the furnaces. It was found, however, that the bricks lining the furnaces were apt to be fluxed at this temperature In the newer boilers the furnaces are water lined and no trouble has been experienced. The boilers cost 16 per cent. of the total cost of the station, and the turbines and electric generators practically cost the same. The steam pressures used are rapidly increasing. American makers are prepared to supply boilers for a working pressure of 1200 lb. per square inch. Turbine makers, however, are unwilling to go beyond a pressure of 600 lb. Their problem, being a dynamical one, is more difficult than the statical problem of the boiler makers. It is stated that the cost of a boiler to work at a pressure of 1000 lb. is about twice as great as that of a boiler for a pressure of 200 lb. per square inch. As yet there is no British station working at a pressure much in excess of 500 lb. per square inch. Sir James Kemnal recently suggested that, with very high pressures, steam drums should be drawn solid and not riveted as they are at present.

MOUNT SINAI has been considered as a site for a third Smithsonian station to study fluctuations of the sun's light and heat, but it has now been abandoned as a possibility. Dr. C. G. Abbot, Assistant Secretary of the Smithsonian Institution of Washington, D C., and Director of the Smithsonian Astrophysical Observatory, has left the Red Sea and finished his tour of India. He is now on his way to South Africa, continuing his search for a suitable site. It is hoped that data obtained from a third station, and later from a fourth, if more funds should become available, will increase the possibility of making trustworthy weather forecasts all over the world, weeks and even months in advance. Data are already being obtained from the study of the sun at Mt. Montezuma on the western slope of the Andes Mountains in Chile, and on Table Mountain in Southern California; and the National Geographic Society has made a third observation station possible by extending financial aid

PROF. FRASER HARRIS, formerly lecturer on physiology in the University of Birmingham, delivered the last of the present series of Monday evening lectures at the Midland Institute on March 8. His subject was "Biology in Shakespeare." Prof. Fraser Harris said that he used the word biology as meaning all knowledge concerning life, vegetable and animal, both in health and disease; but for the purposes of the lecture, he would not include any references to botany, zoology, or medicine. He did, however, include one or two allusions to surgery, the most interesting of which were the lines spoken by the Archbishop of York in "Henry IV.":

> "If we do now make our atonement well,
> Our peace will, like a broken limb united,
> Grow stronger for the breaking."

References to the physiology of the following were studied in the plays—sleep, the heart, arteries, veins, and nerves; fainting, the doctrine of the three kinds of spirits, the halitus sanguinis; the action of alcohol; digestion; starvation; the description of Falstaff's death; infection; first aid; the vis medicatrix naturæ; the pia mater and the visceral distribution of the emotions. The physiological psychology of visual hallucination; trophism of nerves, sense before motion; retinal fatigue; the Sauson images; giddiness; psychical blindness and paraphasia were also illustrated by references from the plays.

THE anxiously awaited report of the Broadcasting Committee under the chairmanship of Lord Crawford and Balcarres was issued late last week (H.M.S.O., Cmd. 2599, price 6*d*.). The terms of reference were "To advise as to the proper scope of the broadcasting service and as to the management, control, and finance thereof after the expiry of the existing licence on December 31, 1926. The Committee will indicate what changes in the law, if any, are desirable in the interests of the broadcasting service." The Committee recommends that after the end of this year, the broadcasting service in Great Britain should be in the hands of a public corporation to be known as the British Broadcasting Corporation, consisting of not more than seven or less than five commissioners nominated by the Crown. These commissioners should be persons of judgment and independence and free of commitments; they should receive adequate remuneration. Advisory committees would be appointed by the commissioners in consultation with appropriate societies and organisations, so that all phases of broadcasting may receive consideration. As regards research, the Committee states that expenditure will govern progress: "Outlay on bold experiment should not be meagre. Research should be constant, both official and unofficial." The Committee was much impressed by the evidence received on the importance of broadcasting in education in its widest sense, and advocates the extension of such facilities, if necessary, by the introduction of special wave-lengths for definite subjects.

FEBRUARY temperature was a record in England, and the observations at Greenwich Observatory published in the Daily Weather Reports of the Meteorological Office and in the Weekly Returns of the Registrar-General show some exceptional results. The mean air temperature for the month at Greenwich was 45°·7 F., which is the highest mean for London or Greenwich in February during the last 156 years, it is 6°·9 above the monthly normal for the 150 years from 1770 to 1919, and in practical agreement with the normal for April. In this long series of years the February mean for 1869 was approximately in agreement with that for 1926, and the only other means of 45° or above were 45°·3 in 1779 and 45°·1 in 1872. There were two days, February 21 and 26, with the shade temperature above 60°, and there were eleven days with the temperature above 55°, there were eight days with the temperature for the 24 hours 10° or more in excess of the normal, while the only days with the temperature below the normal were February 9 to 14. The minimum or night temperature was above 40° on seventeen nights, and there were only two nights, February 13 and 14, with frost in the shade. On two days, February 22 and 26, the black bulb thermometer in the sun's rays exceeded 100°, the respective readings being 106° and 111°, but the duration of bright sunshine for the month was small, registering only 1·3 hours a day on the average, while the normal is 2·0 hours Separating the mean of 150 years into periods of 50 years, the means at Greenwich for February are 38°·1 for 1770–1819, 39°·0 for 1820–69, 39°·4 for 1870–1919; the mean for the 150 years is 38°·8. The normal for 35 years, 1880–1915, in general use by the Meteorological Office is 39°·8.

ACCORDING to the *Weekly News Bulletin* issued by the U.S.S.R. Society of Cultural Relations with Foreign Countries, preparations are being made for the celebration of the eightieth birthday of Dr. A. P. Karpinsky, who has been a member of the Academy of Sciences for forty years and its president for the past ten years.

BESIDES the earthquake felt at Comrie at 4·24 A.M. on February 21 (NATURE, March 6, p. 355), it is now stated that a second and perhaps slightly stronger tremor occurred at about 7·40 P.M. on the following day. Both were felt at Lawers, two miles east of Comrie, and at St. Fillans, four miles to the west. The epicentres probably lie about a mile to the west or north-west of Comrie, and close to those of the remarkable series of earthquakes in 1839 and the following years, thus showing a slight displacement to the west since the shocks of 1895 and 1898

THE discovery has been announced, by the New York correspondent of the *Times*, of the element of atomic number 61, by Dr. B. S. Hopkins and others, of the University of Illinois, apparently by the use of X-ray methods. The full account of the work will be awaited with much interest, for element No. 61 belongs to the group of 'rare earths,' the separation of which has always been unusually difficult owing to the close resemblance in properties of the individual elements. On the evidence of high-frequency spectra, it has been shown that the group consists of fourteen elements ranging from lanthanum (At. No. 57) to lutecium (At. No. 71), with a gap represented by element No. 61. Prof Hopkins' discovery would apparently complete the group.

AT a meeting held at the Institution of Civil Engineers on March 5, the organisation of a body to deal with questions of fuel technology was discussed. The proceedings were opened by Sir William J. Larke, of the National Federation of Iron and Steel Manufacturers, who referred to the widely divergent character of fuel practice in industry, and emphasised the need for a body aiming at co-ordination of existing knowledge on the subject. Sir Philip Dawson stated that the fuel bill is a dominant factor in industry; it forms 35 per cent of the production costs in the iron and steel industry; 50 per cent. in the generation of electricity; and 30-45 per cent. of locomotive costs on railways. Sir Richard Redmayne also supported the suggestion for the organisation of an institution of fuel technology, and a committee was appointed to discuss preliminaries and to decide the question of collaboration with the Institution of Fuel Economy Engineers.

IN 1922 the staff of the Research Laboratories of the General Electric Co. Ltd , Wembley, decided that in making communications in scientific journals, the most appropriate method of recognising the co-operative conditions under which their research work is conducted was by expressing authorship as in the name of the whole of the staff Mr. C. C. Paterson, Director of the Laboratories, now informs us that this formula has been misunderstood, and objections have been urged against it even by those who agree with it in principle. A change is therefore to be made, and the formula " by . . . (Communication from the Staff of the Research Laboratories of the General Electric Company, Wembley) " has been selected

THE Council of the Institution of Mining and Metallurgy has made the following awards: The gold medal of the Institution to Sir Robert N. Kotzé, Government mining engineer for the Union of South Africa, in recognition of his distinguished services to the mining industry, with special reference to his work on the dust problem in the mines of the Rand, and of his public work in promoting the development of the natural resources of the Union of South Africa; " The Consolidated Gold Fields of South Africa, Ltd." gold medal to Prof. L. H. Cooke, in recognition of his services, extending over many years, in the advancement of the science and practice of mine-surveying and the improvement of surveying instruments, and of his valuable contributions to the literature on the subject; " The Consolidated Gold Fields of South Africa, Ltd." premium of forty guineas to Dr. H. C. Boydell for his paper on " The Rôle of Colloidal Solutions in the Formation of Mineral Deposits "

THE Geological Society of Peru, which was founded at Lima in July 1924, has issued the first volume of its *Boletin*. The report of the second meeting includes a speech by the President of the Republic, who attended to express his sense of the value of a geological society to a country so rich in mines as Peru. The first printed paper, on some fossil shells from the Cretaceous and Eocene of Peru, is by the president of the Society, Dr. C I. Lissón, professor of geology in the School of Engineers of Lima. He also writes at length on the palæogeography of Peru, and publishes a series of maps of the country at successive geological periods. Among other papers on Peruvian geology may be specially mentioned a valuable summary of the deposits yielding petroleum, by Mr. R. A. Deustua. The publication is well printed and illustrated, and shows that the Society has made a good beginning. To our congratulations we would add our best wishes for its continued success

THE United States Department of Agriculture Library has recently issued an author and subject index covering the publications of the Department of Agriculture on plant pathology up to January 1, 1925, exclusive of the publications on the diseases caused by insects. In the author arrangement all anonymous and some ephemeral publications have been omitted. The subject index aims at giving a complete record of the publications of the Department on plant pathology. Some selection has been made for subjects upon which there are many contributions, the brief and less important ones being omitted. For subjects on which there are few publications, all have been included. The index covers 158 pages of close type-script, a preliminary account being given of the various series of reports and bulletins that are dealt with. Some of the more recent papers are now available for free distribution, and many of the others may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D.C., though most of the early series are entirely exhausted. The Library of the Bureau of Plant Industry is interested in establishing exchange relations with other institutions which issue publications on plant pathology and other subjects pertaining to the work of the Bureau.

A COMPACT and ingenious soil testing outfit has just been put on the market by the British Drug Houses, and should prove of considerable value to farmers and research workers who may need to get a rapid indication of acidity or alkalinity in field soils. The outfit consists of a small double-chambered porcelain boat, a porcelain spatula, and a dropping bottle of B.D.H. soil indicator. The soil and indicator are carefully mixed in the larger end of the boat, allowed to settle and the supernatant liquid decanted into the smaller end, where the colour may be observed readily. The colours range from red with a very acid soil, through orange and yellow, to green in a neutral soil, while alkalinity is shown by blue. The first three colours indicate that lime is needed to improve the fertility of the soil. Tests made with the outfit show that it is practical in type, is easily worked, and that the colour differences are clear and sharp, making it specially useful to observers who are not experienced in the manipulation of scientific apparatus.

MESSRS. Ogilvy and Co. have sent us the third edition of the pamphlet on how to use the microtome, prepared by Prof. S Becher of Giessen, which is issued by Messrs. Leitz. It is an eminently practical compendium which describes clearly how to imbed tissues in paraffin and celloidin and how to use the various forms of microtomes made by Leitz; and most microtomists will probably find in it some small points which they have not heard of or have forgotten. To beginners it should certainly be useful. The only serious defect is that it does not mention the Cambridge rocking microtome, the practical excellence of which seems scarcely to be realised outside Great Britain. Fixation and staining are dealt with only incidentally, but we note that Prof. Becher thinks highly of some nuclear stains (naphtopurpurin, etc.) which are not well known here. The translation is quite clear if not always idiomatic: for English readers reference should have been made to Lee and Gatenby's "Microtomists' Vade-Mecum" rather than its collateral, P. Mayer's "Zoomikrotechnik."

MESSRS. W. Watson and Sons, Limited, 313 High Holborn, London, W.C.1, have recently issued a catalogue of optical and other scientific instruments, with which is combined a dictionary. The latter contains all the descriptions and illustrations included in the "Dictionary of British Scientific Instruments," issued by the British Optical Instrument Manufacturers' Association, and referred to in our columns (NATURE, May 12, 1921, pp. 324-5) shortly after its publication. The combined catalogue and dictionary forms a work of reference which should be of great value and interest to the users of scientific apparatus. The catalogue contains a typical selection of instruments manufactured or supplied by Messrs. Watson. These cover a very wide range and include magnifiers and microscopes, telescopes and field glasses, optical projection apparatus, nautical and meteorological instruments, drawing and surveying apparatus. Among the newer instruments is the 'Binar' pocket combined telescope and magnifier. This consists of an achromatised object glass and a focussing eyepiece, and gives a magnification of 2½ diameters. The object glass alone can be used as a magnifier of about 6 diameters. The telescope is of such small dimensions that it can easily be carried in the waistcoat pocket. The 'Window' telescope is a lens of 15 in. diameter which can be placed in contact with the glass of a window. By its means, observers within a room may conveniently obtain a magnified image of distant objects visible from the window, and thereby the attractions of a house with a pleasing outlook become enhanced.

READERS interested in books relating to the Near East and Egypt should obtain Catalogue No. 476 of Mr. F. Edwards, 83a High Street, Marylebone, W.1, which gives particulars of nearly 900 works concerning Egypt, Mesopotamia, Arabia, Palestine, Asia Minor, the Balkan States, the Sudan, etc.

THE latest catalogue (No. 265) of Messrs. W. Heffer and Son, Ltd., Cambridge, contains the titles of some 1600 books and journals relating to mathematics, physics, astronomy, chemistry, and chemical technology. It should be useful to those requiring publications in the sciences named; also for reference.

MESSRS. C. BAKER, 244 High Holborn, London, W.C.1, have sent us a new issue of their well-known classified catalogue of second-hand scientific instruments. It contains a noteworthy collection of physical and related apparatus, and in particular there is a large number of student's microscopes and accessories. A special catalogue of this section can be obtained post free on application.

MESSRS. Crosby Lockwood and Son announce "The Science of Flight and Practical application," 2 vols., by Capt. P. H. Sumner. The work will be a study of the principles of flight and practical aircraft. Vol. 1, dealing with airships and kite balloons, will be published shortly. The same publishers will also issue "Hydrology," by J. M. Lacey, treating of rainfall and the influence of its distribution on the earth.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Two junior engineers at the Forest Products Research Laboratory, South Farnborough, Hants—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (March 20). A senior technical assistant for experimental work at Greenock in connexion with high-speed internal combustion engines of a special type—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1 (March 20). A number of assistant electrical engineers in the Admiralty Service—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1 (March 20). A head of the Engineering (Production) Department of the Joint Technical College under the Wolverhampton and Staffordshire Education Committees—The Director of Education for Wolverhampton, Wolverhampton (March 20). A senior botany mistress at James Allen's Girls' School, East Dulwich Grove, S.E.22—The Headmistress (March 30). A physiological botanist and a biochemist under the Government of Madras (Development Department), for research work on cotton—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (April 1). A pathologist under the Manchester Committee on Cancer—The Chairman, Manchester Committee on Cancer, 1 Mount Street, Manchester (April 3). A professor of physics in the University College of South Wales and Monmouthshire—The Registrar, Cathays Park, Cardiff (April 17). A warden of the College House of Bedford College for Women—The Secretary, Bedford College for Women, Regent's Park, N.W.1 (April 30). An assistant in the department of entomology (Division of Tropical Medicine and Hygiene), London School of Hygiene and Tropical Medicine—The Secretary, 23 Endsleigh Gardens, W.C.1 (May 31). A chemical laboratory assistant in the Experimental Department of the Fine Cotton Spinners' and Doublers' Association—F. P. Slater, Rock Bank, Bollington, near Macclesfield. A teacher of engineering subjects at the Wandsworth Technical Institute—The Principal.

Our Astronomical Column.

RECENT MAGNETIC DISTURBANCE.—A magnetic disturbance was recorded at Greenwich on March 5, commencing at 10 hr. and lasting until 6 hr. on the following morning. The most disturbed part of the magnetograph traces was between 16 hr. and 23 hr. on March 5, when the extreme range in declination amounted to 53′. The disturbance is thus somewhat inferior to those commencing on January 26 and February 23, but is of interest on account of its apparent connexion with a large sunspot in solar latitude 27° south, mentioned in NATURE of March 6, p. 356. The magnetic disturbance began when the spot was 21° or 1·6 days west of the sun's central meridian.

ENSOR'S COMET.—The absence of any reports of European observations of this comet is cause for surprise. It was easily seen at Johannesburg in bright twilight towards the end of January, and it should have been equally bright early in March. The morning sky has been generally cloudy in England, but Dr. W. H. Steavenson utilised a clear interval on the morning of March 5 to search for it; he found no cometary object as bright as magnitude 9 within 30′ of the tabular place. Assuming that no error was made in setting, this would indicate a very unexpected decline in light. This would not be unprecedented; Westphal's comet underwent a similar mysterious loss of light in the autumn of 1913. Further observations are desirable before the fact is regarded as established. Mr. G. Merton noted that the comet approached Mercury within a tenth of a unit about February 11. The mass of Mercury is, however, too small to produce any appreciable disturbance at this distance.

THE MEASUREMENT OF STELLAR RADIATION.—An interesting article by Dr. Hale on "Heat from the Stars" is published in *Scribner's Magazine* for January. After an historical introduction, the work of the late Prof. Nichols with the radiometer is described, and an amusing reminder of the great sensitiveness even of his early type of radiometer is afforded by the remark that the observed deflexion due to the heat radiation from a human head 2000 feet distant was as much as 25 millimetres. Work with thermo-couples by Pfund, Coblentz, and Pettit and Nicholson is next described: the sensitiveness of the instrument used by the two latter observers being so great that the radiation from stars even so faint as the thirteenth magnitude has been measured. Finally, after an account of Abbot's work on the energy distribution in stellar spectra, Dr. Hale explains the relation between facts obtained in the manner described and theories of stellar constitution and life-history, as exemplified by the work of Eddington and Jeans. The article is well illustrated and interestingly written for the general reader, forming a useful summary of the work accomplished up to the present time in this department of astronomy.

NOVA PICTORIS.—*Astr. Nach.*, No. 5413, contains an interesting paper on this star by Prof. J. Hartmann of the La Plata Observatory. The position is given as R.A. $6^h\ 34^m\ 56^s{\cdot}58$, S. Decl. $62°\ 34'\ 32''{\cdot}7$ (equinox 1925·0). Magnitudes of the star are tabulated from 1925, May 27 (mag. 2·8) to Nov. 23 (mag. 4·4). The principal maximum (mag. 0·96) was on June 9; there were secondary maxima on July 28 (mag. 1·8) and Aug. 10 (mag. 2·3). The star remained conspicuously visible to the naked eye for more than seven months, which is longer than the duration of most recent novæ.

Prof. Hartmann elaborates a new theory of novæ; a great increase of temperature is supposed to arise in the star's central regions, causing a rapid expansion of the surface. In the present case the radial velocity due to this expansion was found to average 140 km./sec. The star's radius prior to the outburst is estimated as 1,400,000 km.; on May 27 this had increased to 141,000,000 km., and on June 9 to 298,000,000 km. Throughout the expansion the surface temperature is assumed to remain unaltered, but after the maximum, cooling sets in and the spectral type changes. Taking the star's original spectral type as A 2, its parallax is found to be 0·0007″, and distance 4500 light-years.

Prof. Hartmann notes that a change of surface temperature from the coolest to the hottest stellar type would account for only one-tenth of the increase of light, so that increase of diameter is also required.

Research Items.

Origin of the Eskimo.—Writing on the results of the fifth *Thule* Expedition, 1921–24, in the *Geographical Journal* for February, Mr. K. Rasmussen believes that the original Eskimo culture must have been of an exclusively inland type, that of a people dwelling by lake or stream. In course of time, either by following the wandering reindeer or driven by hostile Indian tribes, the aboriginal Eskimo moved to the Arctic shores, adapting their implements to the needs of hunting in the sea and on the ice. Reindeer appear to have led them to the region between Coronation Gulf and Boothia peninsula. From there they moved west to Alaska and east to Greenland. The belt of tundra west of Hudson Bay barred the passage of one large group now known as the Caribou Eskimo, among whom the aboriginal inland culture has been preserved. The Eskimo who moved to the coast evidently flourished, and hence their extensive migration west and east. Finally, in comparatively recent times, a new migration has taken place from the interior down to the coasts. These conclusions are in close accordance with the views first advanced many years ago by Prof. Steensby. The papers contain a summary of the main results of the expedition and has several photographs of the Caribou Eskimo.

Spirit Worship in the Nilgiris.—In the *Indian Antiquary* for January, Rai Bahadur B. A. Gupte gives an account of a curious family of 'Pariahs,' who lived in the Nilgiri Hills about twenty years ago, two of the members of which were said to be spirit-possessed, and to have certain powers. Not only did they profess to foretell the future, but they also claimed to be able to ward off calamities, exorcise demons, give children to the barren, and regulate the sex of unborn children. Their influence was so great that although 'untouchables,' Brahmans and their womankind mixed with them freely. The possessed members were the younger son and younger daughter, the former by Mariamma, the goddess of cholera, and the latter by Kani-amma, the virgin goddess. Mariamma, ferocious and wild, was represented as a widow who guided Kani-amma, who was fair, young, and attractive. A small hut was set out as a shrine of Mariamma, who was represented by a small stone figure about 9 inches high. The author witnessed several performances by the family in one of which the goddess, speaking through the girl, answered questions propounded by him; in another the son as 'god' went through a dancing performance in the course of which he stood on the edge of a scythe. No mention is made of the more violent symptoms usual in 'possessions.'

Geography of Wisconsin.—Wisconsin has an active Geological and Natural History Survey which has been responsible for several memoirs on the State. The latest of these is a well-illustrated volume, published by the State at Madison, on the geography of south-western Wisconsin (Bulletin No. 65), by Mr. W. O. Blanchard. The various geographical factors of topography, soil, climate, mineral resources, and position are treated in turn by an author with a wide personal knowledge of the country. The result is a lucid explanation of the past and present economic conditions and distribution of population. Another publication by the same society (Bulletin No. 67) is a brief outline of the geography of the whole State by Mr. W. O. Hotchkiss and Mr. E. F. Bean. This is written in a more popular style, but forms a useful summary.

Prenatal Death and Sex Ratio in the Pig.—Dr. F. A. E. Crew (*Proc. R. Soc. Edin.*, vol 46, pt. 1) finds that the primary sex ratio in pigs is at least 60 per cent., 150 males to every 100 females being produced as a result of fertilisation, due either to a differential production of the two sorts of spermatozoa or a differential functional activity on the part of these. There is a serious prenatal mortality affecting chiefly the males and operating in such a way as to make the secondary sex ratio practically equality. The reason for this higher male death-rate the author believes to be fundamentally genetic in its nature, and suggests that the male type of physiology is less able to withstand the stress of functioning both prenatally and postnatally than is the female. His results confirm those arrived at by Parkes in a similar inquiry.

Asymmetry in Mammalian Skulls.—Mr. A. B. Howell (*Proc. U.S. Nat. Mus.*, vol. 67, art. 27) has investigated very thoroughly four mammal skulls which exhibit definite asymmetry, two primates and two pinnipedes. From his examination of this material the author concludes that the primary cause inducing asymmetry in the skulls of mammals is probably accident or disease to the bones or muscles of one side of the head at an early age, of such a character as to result in a stunted or infantile condition of a crucial part of the bony framework and a reduction in the rate of growth, or strength, through lesions, of the corresponding muscles. The normal development of the bones of the skull is directly dependent upon the growth of the attached muscles. If the latter for some reason or another remain infantile or fail to grow, the bones to which they are attached will remain proportionally undersized. In the four skulls examined, the original seat of the injury was in the neighbourhood of one of the glenoid fossæ, and the author discusses the relations of the temporal and masseter muscles in their size and strength with the extent of the asymmetry observed in the skulls.

The Vascular System of the Myxinoids.—Prof. F. J. Cole has continued his systematic study on the myxinoid fishes, and in pt. vi. (*Trans. Roy. Soc. Edin.*, vol. 59, pt. ii., 1925) of his monograph presents a detailed and excellent account of the vascular system of Myxine. Many important new features are brought out. Asymmetry of the veins is of constant occurrence, with the result that vessels which are not homologous perform the same functions on the two sides of the body. A third pair of local hearts is described in relation to the cardinal veins, in addition to the previously known unpaired portal and paired caudal hearts. The cardinal hearts are sacs formed by swellings of the veins in question, guarded by valves, and possessing extrinsic structurally modified muscles. In the possession of an extensive lacunar system, myxinoids are specialised, and a complete account of this system is now available for the first time. These lacunæ are lined by endothelium and are divisible into red and white lymphatics. The former always contain red blood which enters them from the arteries, and they also communicate with the veins by valved apertures. They form, therefore, part of the blood vascular system interposed between the arteries and veins and take the place of a closed capillary system, which is absent in those regions where these lymphatics occur. The dominating feature of this system is an extensive subcutaneous sinus, so that the animal lies in its skin as in a loose sac. The white lymphatics represent a true lymphatic system corresponding to that of higher vertebrates. It forms a complete system in itself, beginning as a blind plexus in the walls of certain organs and discharging finally into the veins, indirectly through the red lymphatics, and also directly via the caudal hearts.

Snow in Eastern Siberia.—To the *Recueil de Géophysique* (vol. 4, pt. 3) of the Geophysical Observatory of Leningrad, M. W. B. Shostakovitch contributes a statistical paper on the snow covering of eastern Siberia since 1881, when regular observations were first made, until 1913. The data, while showing a distinct correlation between the thickness of the snow covering and the quantity of winter precipitation, prove that various factors have importance. Topographical features have great influence; on windward slopes the snow cover is greater and on leeward slopes less than the precipitation would suggest. Most interesting, however, is the conclusion that the annual variation in thickness of the snow cover is especially great in regions where snow is comparatively scarce. February is the month of maximum thickness, the depth of snow in that month averaging 10 cm. to 20 cm. in the Amur valley, except at the mouth, where it rises to 70 cm., and increasing generally towards the north-west and north-east but keeping comparatively shallow in the Okhotsk district and Lena valley. Practically the whole of eastern Siberia, except the east coast, has a snow covering for at least 150 days a year, the duration increasing with latitude to 250 days.

Isostasy in Western Siberia.—In 1912 the Russian Astronomical Society sent an expedition to Western Siberia to determine the force of gravity at various stations. From the results obtained, isostatic reductions have now been made by Wm. Bowie and his co-workers (*Am. Journ. Sci.*, Feb. 1926, p. 113). The remaining anomalies are very small, and provide further support for the view that isostasy obtains for all portions of the earth's crust. The data for Siberia and for other regions are conveniently summarised in a table, part of which is here reproduced. The figures refer to the number of gravity stations and to the mean anomaly in dynes with regard to sign.

United States	296	−0·006
Southern Canada	42	−0·009
Northern Canada	9	+0·001
India	73	−0·004
Holland	51	−0·001
Alps and vicinity	31	+0·019
Western Siberia	9	−0·005
To these may be added,		
Southern Pacific Islands	5	+0·030

This last result should probably be reduced by one-half to take into consideration the much higher density of Pacific as compared with continental rocks (*Journ. Wash. Acad. Sci.*, Dec. 4, 1925).

Echo Soundings in the Indian Ocean.—In the waters to the south of Java and Bali and around Christmas Island, where soundings hitherto have not been numerous, several hundred echo soundings were taken last autumn from four Dutch submarines and the depôt ship *Pelikaan*. An account of the work with a chart of the waters is published in *Verhandelingen* No. 17 of the Royal Observatory of Batavia. The instruments used were those generally employed for submarine communication between vessels. Several observations being made for each determination, the time error was reduced to about 0·1 second. The few previous soundings on the whole agree with the echo soundings; occasional discrepancies may be due to inaccuracies in the geographical positions of the earlier work. The regularity of the submarine contours in a region with great differences in depth suggests the reliability of the echo work. A remarkable result is the discovery of a row of submarine elevations in about lat. 11° S., or more or less in a line with Christmas Island, and immediately to the north of them a long steep-sided trough of more than 3800 fathoms and reaching in one place to 4107 fathoms.

The Determination of the Wave-lengths of X-rays by Means of a Reflection Grating.—Doan and Compton have recently observed the diffraction of X-rays falling on a metallic grating at a very small angle with the surface, and, in the *Comptes Rendus Acad. Sci.*, Paris, January 4, M. J. Thibaud describes measurements made on the $K\alpha$ and $K\beta$ copper rays, using a plane glass grating with 200 lines per mm. with a width of less than 4 mm. The angle between the rays and the surface of the grating was less than the limiting angle for total reflection, and the photographic plates showed two broad stripes corresponding to the direct and the totally reflected rays, and a diffraction spectrum with remarkably fine lines. The wave-length for the line $K\alpha$ Cu was determined as $\lambda = 1{\cdot}540$ Å U, correct to about 1 per cent., while measurements on diffraction in crystals, using the accepted values for their lattice constants, give 1·538 Å. The Compton effect did not appear to influence the result, and theory shows that any such influence would be extremely minute for the angles employed.

A New X-ray Spectrograph.—At the meeting of German physicists in Danzig in September 1925, Dr. H. Seeman of Freiburg described a new X-ray spectrograph without a circular scale, which allowed its zero point to be accurately determined, did not depend on focussing, and could be used with crystal surfaces far from perfect. His paper appears in the issue of the *Physikalische Zeitschrift* for January 21. The camera holding the plate on which the diffraction photograph is taken is bounded on one side by a plane surface at right angles to the plate. On this plane surface a bridge-piece, in the centre of which the crystal is fastened, can slide. The surface of the crystal is adjusted to be nearly parallel to the plane surface. In front of the surface of the crystal is a knife edge, the distance of which from the crystal can be adjusted. The X-rays fall on the crystal at an angle of 10°-20° to the surface, and the knife edge prevents their direct access to the plate. Two photographs are taken, the crystal being rotated through 180° about an axis perpendicular to the plane side of the camera by moving the bridge on the plane. A wider beam is used in determining the zero. The author describes two other methods of using the camera: one, which he calls the 'pin-hole camera,' suitable for all X-rays, and the other a transmission method suitable for thin crystals and X-rays they do not absorb.

Fibrous Crystals of Sodium Chloride.—We have received a communication from Mr. L. McCulloch, of the Research Department of the Westinghouse Electric and Manufacturing Co., Pittsburgh, in which he refers to the statement by Ruskin, quoted by Prof. Desch in his British Association address on the chemistry of solids (see Nature, Oct. 24, 1925, p. 610), to the effect that whilst red cuprous oxide may sometimes form fine hair-like threads, sodium chloride and other cubic minerals never assume such a form, the statement being used to illustrate the imperfection of our knowledge of the cause of variations of habit among minerals. Mr. McCulloch sends photographs of columnar or fibrous crystals of sodium chloride, obtained by growth in an acid gel prepared by mixing a solution of sodium silicate with hydrochloric acid. These crystals are slender rods, several millimetres long, with cubic terminations. Such crystals have been prepared on several occasions, one of the earliest records being that of A. Knop, who records hair-like crystals of potassium chloride in his "Molekularconstitution und Wachstum der Krystalle" (1867), whilst others are recorded by O. Lehmann in his "Molekularphysik" (1889). The presence of gelatinous material favours elongated growths, and many observations of the kind are found scattered through the literature. One of the photographs shows curving and distortion of the rods, which is also characteristic of growths in gels.

SAMUEL HAHNEMANN AS A CHEMIST.—At the request of some of his medical friends, Prof. E. O. von Lippmann has investigated (*Chemiker-Zeitung*, 1926, Nos. 1 and 4) the chemical knowledge of Samuel Hahnemann, the founder of homœopathy. In books on the subject, Hahnemann is often described as an accomplished chemist, and the investigations of von Lippmann show that the title is well deserved. So far as chemistry is concerned, Hahnemann was entirely self-taught, but he nevertheless made rapid progress, and was one of the first to realise that a training in chemistry is of the greatest importance to the medical student. In 1784 he undertook the production of a German edition of a work by Demachy (1728–1803), entitled "L'art du Destillateur des eaux fortes" (Paris, 1773), and called it "Der Laborant im grossen, oder die Kunst, die chemischen Produkte fabrikmassig zu verfertigen." This book, which is a kind of technological text-book of the most important chemical preparations, and is by no means concerned merely with acids, was enriched by Hahnemann with a large number of original contributions. Among these may be mentioned the detection of hydrochloric acid by means of silver sulphate, and of sulphuric acid with lead chloride; the estimation of sulphuric acid and other chemicals by means of specific gravity determinations; and a clear realisation of the importance of the newly-discovered 'fire-air' in the process of combustion. Hahnemann devised also a method of estimating arsenic by precipitating it in the form of its sulphide from a solution made weakly acid with hydrochloric acid, and gave the alternative method of precipitation with an ammoniacal solution of copper. About 1788 he invented the sulphuretted hydrogen test for the presence of lead in wine. Although Fourcroy had suggested the same test, he was not able to overcome the difficulty that iron might interfere with it, whereas Hahnemann showed that by making the wine weakly acid with spirit of salt, the iron would not be precipitated. Hahnemann carried out many more pieces of chemical research, notably an investigation of silver nitrate, and von Lippmann concludes that he possessed an uncommonly good knowledge of the science. It is noteworthy that, so early as 1792, he is described in Crell's "Annalen" as a celebrated analytical chemist.

THE ALGEBRAIC NUMBERS AND DIVISION.—In his presidential address to Section A of the American Association for the Advancement of Science at the recent Kansas City meeting, Dr. J. C. Fields, of the University of Toronto, lectured on "The Algebraic Numbers and Division." The modern theory of algebraic numbers had its origin about a hundred years ago in attempts to prove Fermat's last theorem, where a crucial difficulty arose through the discovery that an integer in an algebraic field is not, in general, uniquely expressible as a product of 'prime' integers in the field. Many attempts to extend the conception of an 'integer' in such a way as to restore uniqueness of factorisation were made by various writers, the matter being finally settled by Kronecker and Dedekind, whose definitions of an 'ideal,' the new entity required for the purpose in view, differed mainly in the matter of notation. More recently Hensel, in his "Theorie der Algebraischen Zahlen," has developed yet another method which has enabled him to obtain the most important known properties of algebraic numbers with remarkable ease. Hensel's method is based on the representation of a number r in the form

$$r \equiv a_i p^i + a_{i+1} p^{i+1} + \ . \ . \ . \ + a_k p^k \pmod{p^{k+1}},\ i \gtreqless 0,$$

where each coefficient a_s is chosen from the integers 0, 1, 2, . . . $p-1$. This p-adic representation holds not only for rational integers but also for rational fractions, and can be extended to apply to algebraic numbers too. In the application to algebraic numbers the general member of a field is taken to be $A_1\omega_1 + A_2\omega_2 + \ . \ . \ . \ + A_n\omega_n$, where A_1, A_2, . . . A_n are p-adic numbers and $(\omega_1, \omega_2, \ . \ . \ . \ \omega_n)$ a basis of the field. By this means Hensel has obtained a complete solution of the problem of resolving a prime number into its prime ideal factors. Most of Dr. Fields' address was devoted to the detailed technicalities involved in the p-adic representation of algebraic numbers. The case of a quadratic field was discussed more fully towards the end of the lecture.

ELECTRIC INDUCTION FURNACES.—The evolution of the electric furnace in which the refractory materials are heated by high-frequency induced currents, and some of the useful applications of this type of furnace, are well described by Dr. Northrup in a paper printed in the February issue of the *Journal of the Franklin Institute*. The earliest form of electric furnace used resistance heating. Then Moissan enclosed an electric arc in a box made of lime and succeeded in obtaining temperatures much higher than those obtained by other methods. He melted and reduced most of the refractory oxides, but unfortunately the resulting substances contained carbon and other impurities which were introduced by the vapours of the arc. In inductive heating, the radiated electromagnetic energy passing through the jacket of heat-insulating material falls on the conducting substance causing eddy currents which heat it. The heat-insulating refractory material used in the crucible is transparent to long-wave radiations but is nearly opaque to the short wave-length heat radiation. The heat thus rapidly accumulates and the temperature elevation becomes very high. With a frequency of 50, the ordinary frequency of supply in Great Britain, the magnetic field used must be very strong, and so iron has to be employed. But with frequencies of 500 or more, we get the 'ironless' inductive heater. At these high frequencies the condensers that have to be used in order that the ratio of the true power supplied to the apparent power may be large are very much smaller, and so their manufacture becomes commercially feasible. The method is specially applicable to very large installations. The Westinghouse Company make ingots of nickel-iron which are practically free from carbon and weigh 225 lb. There are a few gas holes in the ingots, but they are free from oxide and, as they weld together under forging operations, no metal is lost in trimming. Tantalum, which fuses at 2900° C., can be readily melted by the inductive method and produced practically free from carbon

Standards in Illumination and Photometry.

AT the meeting of the Illuminating Engineering Society held on February 25, a series of communications were presented reviewing recent British Engineering Standards Association's specifications dealing with illumination and photometry. Mr. P. Good, in an introductory paper, explained the aims and objects of the Association. In arranging for the preparation of standards, the Association does not act on its own initiative, but only on demands from outside; for example, from a representative trade organisation, a technical society, or a Government Department. When the British National Committee of the International Illumination Commission invited the Association to carry out standardisation in the field of illuminating engineering, a conference of all interested parties was called. The formation of a Sectional Illumination Committee was the immediate result of this conference, held in January 1924. This Committee is thoroughly representative, and the fact of many of its members being also members of other bodies or committees interested in illumination is favourable to co-operation and avoidance of overlapping of work. Specifications for portable photometers[1] and for industrial lighting fittings for electric lighting,[2] and a glossary of terms[3] used in illuminating engineering and photometry, have already been issued. Three other committees, concerned with illuminating glassware, street lighting, and photometric integrators, are actively at work but have not yet reported.

Papers summarising the three reports so far issued were then presented by the chairmen of the respective committees. Lieut.-Col. Edgcumbe, in dealing with the specification for portable photometers, pointed out that it opened new ground. Two broad classes of photometers are recognised: (*a*) for exterior work (for example, street lighting) where a range of 0·01 to 2 (or preferably 5) foot-candles is necessary, and (*b*) for interior use, where the range should be 0·2 to 20 foot-candles, or preferably higher. Provision for measurements of brightness as well as illumination is also desirable; the former should preferably be expressed in candles per square inch. The author discussed in some detail the nature of the test-screen, and the problem of obtaining a surface which would approach 'perfect diffusion,' and therefore have the same brightness when viewed at all angles. In practice it is found necessary to limit the angle of view, and the test-surface should be capable of being placed at least 4 ft. from the photometer and still fill the whole of the field of view. Other clauses prescribe the use of an ammeter to enable the current through the lamp in the instrument to be maintained constant, and the light from the lamp should have a colour similar to that of a metal filament lamp run at 9 lumens per watt. In conclusion, the various sources of errors in portable photometers were discussed, and it was shown that their additive effect may amount to so much as ±20 per cent. In practice, however, it is unlikely that all errors will be in the same direction, and therefore an all-round accuracy of ±15 per cent. seems a reasonable requirement.

Lieut.-Commdr. Haydn T. Harrison, dealing with the specification for industrial reflector fittings for electric lighting, explained that the main object is to standardise a form of reflector to assist the excellent work of the Home Office Departmental Committee in promoting improved lighting in factories and workshops. The most suitable type of reflector for this purpose appears to be the 'R.L.M.' form, having the following main features: (1) The source of light can be made invisible above a definite angle of cut-off, (2) at the angle where the filament is visible it is viewed against a highly illuminated white reflecting surface; and (3) the reflecting surface, being of vitreous enamel, is easily cleaned. If properly constructed and used, such reflectors should enable sufficient illumination to be provided without undue glare. But it is to be noted that the screening of filaments depends on the latter being in the correct position within the lamp bulb; hence the tolerances allowed in the B.E.S.A. specification for electric lamps are of importance. It was also pointed out that the adoption of forms of reflectors ensuring adequate screening naturally involves some increase in the absorption of light, and consequently a somewhat lower efficiency. Thus if the angle of cut-off be 20° instead of 17½°, as is customary in America, the efficiency may be only sixty per cent. as compared with seventy per cent. for the smaller angle. In comparing different forms of reflectors in terms of efficiency, due consideration must therefore be paid to the completeness with which the filament is screened from the eyes of operators.

The contribution dealing with the glossary of terms used in illuminating engineering and photometry was presented by Mr. P. Good, in the absence of the chairman of this committee (Mr. J. W. T. Walsh). The author directed attention to the stumbling-block of language in dealing with international affairs. Unfortunately the 'scientist-engineers' are apt to set up new towers of babel with every advance in knowledge. In illuminating engineering, the importance of common agreement on terms and definitions is very great. In reviewing the list, Mr. Good explained that it inevitably involves some degree of compromise, and it was shown that, whilst adhering to British methods, efforts have been made to bring the list into line with international and foreign practice. The first term (luminous flux) is fundamental. The term 'flux' to convey the notion of time has been so widely adopted that it appears to the committee preferable to substitute 'radiation.' Nevertheless, as 'luminous flux' has become such a familiar phrase in illuminating engineering, it was ultimately decided to retain it.

The three papers led to a keen discussion, in which Mr. C. C. Paterson (chairman), Lieut.-Col. Kenelm Edgcumbe, Mr. H. Buckley, Mr. G. Campbell, Mr. R. A. Ives, Lieut.-Col. Silvester Evans, Mr. H. C. Allpress, Mr. T. E. Ritchie, Mr. A. Cunnington, M. H. H. Long, Capt. W. J. Liberty, Dr. D. H. Ogley, Mr. L. Gaster, and others took part. The views expressed were generally favourable to the main conclusions of the specifications, though the exact application of the 'cut-off' angle in the case of industrial reflectors was the subject of some discussion. At the conclusion of the meeting a variety of reflectors designed to comply with the requirements of the specification were shown, and a number of portable photometers were exhibited. The latter included the most recent form of 'Holophane Lumeter,' in which various modifications to enable the instrument to comply completely with the specification have been embodied. A novel accessory shown for the first time was the test-plate fitted with a device to enable the angle of incidence of light-rays from the source to be determined. A very simple form of portable photometer recently developed in France (the 'Niam' photometer) was also shown.

Work of the Glass Research Association.

WE have recently received No. 14 of the Bulletin of the Glass Research Association, actually dated July 1925. The distribution of these copies to the press marks a departure from the practice of the Association, but there appear good reasons for so doing. The Association, when it found in 1924 that further Government financial assistance could not in the future be relied on, decided to wind up its activities, and it was clearly desirable that a résumé should be prepared, both for its members and for the scientific public, of the work which it had been able to accomplish. The copy of the Bulletin before us supplies this résumé, and we may add that it appears to have been done in a very efficient manner, the system of classification of the results adopted enabling the reader to grasp the facts readily.

The work of the Association was carried on in the laboratories of the Association itself and also in co-operation with the National Physical Laboratory, with the Department of Glass Technology, Sheffield, with two other research associations, namely, the British Refractories Research Association and the British Cast Iron Research Association, and, finally, in a single investigation on the subject of the efficiency of manual workers, with the Industrial Fatigue Research Board The National Physical Laboratory was responsible for several papers on the physical properties of glasses, covering the subjects of viscosity, thermal endurance, and elastic and viscous movements in glass. Special mention may be made of the researches on the viscosity of glass, since they covered a wide range of temperature and led to very interesting results.

Investigation of a whole series of problems of a fundamental character involving the processes of glass-melting were carried out at Sheffield, and results, important alike for practice and for theory, were the outcome. Of the work carried out in the laboratories of the Association, the one criticism that occurs to the present writer as he peruses the summary is that it covered so wide a range and appears to have involved so many ambitious programmes, that a number of investigations seemed to halt at intermediate post houses. Nevertheless, a great deal of useful information appears to have been passed on to the glass industry by the Association's workers.

We understand that most of the completed papers presented to the Association will eventually receive full and open publication, and there is no need, therefore, to examine the results of research in detail. The results so far obtained suggested to Research Committee A the direction in which future researches on glass might be planned, and a report signed by the chairman is appended to the Bulletin, suggesting to scientific workers that future investigations might be pursued on the subject of the constitution of glasses, using such methods as the determination of the viscosity, electrical properties or surface tension, the behaviour of glass under electrolysis over a wide range of temperature, a study of X-ray diffraction patterns and of heating and cooling curves obtained under various conditions. Other subjects needing investigation as having more or less direct practical application included the mechanical properties of glass in relation both to composition and to treatment, the thermal properties of glass at all temperatures up to the melting temperature, and the solubility of gases in glass at various temperatures and pressures, their mode of evolution and absorption and their effect on the physical properties of the glass.

A number of suggestions of a practical character are also appended in a note by the chairman of the Refractory Materials Research Committee.

Physical Factors in Mosquito Ecology.

IN the *Bulletin of Entomological Research*, vol. 16, pt. 3, pp. 187-248 (January 1926), Mr. R Senior-White contributes an important paper on this subject which should receive attention from all concerned with mosquito control. The author finds that, in Ceylon, natural waters exhibit a range of hydrogen ion concentration the *p*H values of which range from 5·4 to 9·2, but, as a general rule, mosquito larvæ only occurred when the *p*H was between 5·8 and 8·6. The *p*H was determined colorimetrically by means of Clark and Lubs' indicators. Species living in moving water have wider tolerances than those of standing water, and the former tolerate higher acidity, and the latter tolerate higher alkalinity, respectively. It also appears that anophelines have wider ranges of tolerance than culicines.

It is, however, less easy to generalise about mosquitoes breeding in artificial waters. Such waters are very diverse: there may be a coconut shell in deep shade, containing acetic acid as the result of fermentation, with water at *p*H 4·4; or there may be a water-butt in full sunlight, its contents green with algæ and giving a *p*H of 9·6+. Under such conditions mosquito larvæ, which are not to be found in natural waters, do occur. The commonest of the artificial-water breeders, *Stegomyia albopicta*, is found to tolerate water right through the entire range of *p*H values tested. The measurement of the "residual" *p*H, *e.g.* the value after bringing the water into gas-equilibrium with the air, is shown to be significant.

Natural-water breeding mosquitoes were thus found to be intolerant of any acidity other than that due to carbon dioxide. The solute-concentration limits were also inquired into and are summarised in terms of conductivity $\times 10^6$ in an accompanying table. Natural-water breeders are all found in water where this figure is below 1000, while artificial-water breeders extend their range into much higher concentrations. There appears to be no sharply limiting factor with respect to dissolved oxygen. In two species, with which a considerable number of observations were made, the data showed that there is a complete tolerance ranging from water with only 0·40 mgm. per litre in the case of ***Anopheles maculatus***, and from 0·87 mgm. in the case of ***A. listoni*** up to super-saturation values of 14·84 mgm. and 12·32 mgm. per litre, respectively. It may be said, however, that waters in which the figure is low are not favoured by anophelines.

In rice fields the presence of ***Anopheles listoni***, the only malaria carrier commonly breeding therein, is shown to be dependent on the presence of a considerable amount of dissolved oxygen, and methods for avoiding this are discussed. The toleration-limits of various species with respect to the above-mentioned factors are discussed at length, and taking ***Anopheles listoni*** as an example the optimum conditions for this species are—*p*H of 6·8-7·0: a conductivity of 300-700 and an oxygen content of 5-7 mgm. per litre. There is shown to be a "feeding-association" of anophelines with certain algæ, on the presence of which that of the mosquitoes probably depends, but these and other points require more space than is available for adequate discussion.

University and Educational Intelligence.

BIRMINGHAM.—Mr. Hugh Donovan, surgical registrar to the Queen's Hospital, has been appointed part-time assistant in the Department of Pathology and Bacteriology.

Gifts recently reported include sums of 50l. each from Sir James Kemnal, the Partington Steel and Iron Co. Ltd., Messrs. Balfour, Beatty and Co., and 50 guineas from Messrs. D. Colville and Sons, Ltd., towards the expenses of the new Fuel Treatment Laboratory in the Coal Mining Department; a model illustrating modern methods of shaft sinking in coal-mines by the François Cementation Co.; and two scholarships of the value of 60l. each, for three years, from Messrs. British Ropes, Ltd., for students in the Oil Engineering and Refining Department.

CAMBRIDGE.—Mr. F. L. Engledow has been appointed a member of the council of the National Institute of Agricultural Botany. Mr. Engledow is a fellow of St John's College; he has since the war been working in the Plant Breeding Institute under Sir R. H. Biffen: his special studies have been in relation to yield in the cereals, effective yield testing and detailed field behaviour of various commercial varieties.

Dr. R. A. Nicholson of Trinity College has been elected to the Sir Thomas Adams's professorship of Arabic, in succession to Prof. E. G. Browne, who died on January 5. Dr. Nicholson was formerly University lecturer in Persian.

LONDON.—The following are among the fellows of University College recently appointed: Mr. J. T. Carter, honorary research assistant in histology, Prof. H. B. Fantham, since 1917 professor of zoology and comparative anatomy, University of Witwatersrand; Dr. Morris Ginsberg, lecturer in the department of philosophy and psychology, and since 1925 University reader in sociology, London School of Economics; Prof. Y. Heyrovský, professor of physical chemistry in the Charles' University of Prague; Mr. L. A. Legros, consulting engineer; Dr. A. G. Levy, physician, City of London Hospital for Diseases of the Chest; Mr. G. Udny Yule, president of the Royal Statistical Society.

The following are among the fellows of King's College recently appointed: Sir James Kingston Fowler, physician to the Middlesex and Brompton Hospitals; Mr. L. B. Atkinson, president in 1920–21 of the Institution of Electrical Engineers and chairman and president-elect of the Electrical Research Association; Prof. W. Wilson, professor of physics at Bedford College.

The following doctorates have been conferred: *D.Sc.* (*Botany*): Mr. M. M. Mehta (Imperial College; Royal College of Science), for a thesis entitled "Studies on Lignification." *D.Sc.* (*Chemistry*): Mr. F. L. Usher, for a thesis entitled "The Nature of the Interfacial Layer between an Aqueous and a Non-Aqueous Phase," and other papers.

MANCHESTER.—Applications are invited for the Lewis Atkinson entrance scholarship in electrical engineering, the annual value of which is 50l. The scholarship is tenable for three years. Forms of nomination and application are obtainable from the Internal Registrar of the University. They must be returned by April 1.

THE Cambridge local lectures available for 1926–27 are listed in a 36-page pamphlet issued by the Board of Extra-mural Studies of the University. The lectures are grouped under the heads: A—natural science, and B—history, geography, political economy, mental science, literature, and art. Four pages are devoted to Group A and twenty-four to Group B. The natural science lecturers are G. P. Bailey (James Stuart lecturer), F. Balfour Browne, H. Yule Oldham, E. A. Parkyn, and Bernard Smith The inclusive fee, covering the lecturer's travelling expenses and, as a rule, everything except strictly local expenses, are 48l.-66l. for a full course of twelve lectures and 33l.-45l for a short course of six. A preliminary programme of the summer meeting, 1926, announces that the main subject of study will be India in ancient, medieval, and modern times, and there will also be lectures and classes in theology, architecture, and geology, and, for foreign students, in English language (including phonetics) and literature The inaugural address will be given on July 29 by the Earl of Ronaldshay.

A PRELIMINARY programme has been issued of the third Congress of the Universities of the Empire, to be held on July 12-16 at Cambridge. The chairman for the morning session of July 13 will be the Earl of Balfour, and the subject of discussion "The State and the University." The afternoon session will be devoted to considering the desirability of establishing in London a school of advanced legal studies (chairman, Viscount Cave). Co-operation in research throughout the Empire, will form the subject of the morning session of July 14, under the chairmanship of the Marquess of Londonderry. The morning session of July 15, under the chairmanship of Sir Matthew Nathan, will be given to a consideration of the mutual recognition of examinations and related topics, while the afternoon session, under the chairmanship of the Duke of Devonshire, will be devoted to the subject of the physical welfare and training of students and the organisation of athletics. At the morning session of July 16, under the chairmanship of the Viscount Cecil of Chelwood, the actual working of the Ph.D. scheme will be discussed, while the afternoon session (chairman, the Viscount Haldane of Cloan) will be occupied with a consideration of the desirability of articulating other pension schemes with the Federated Superannuation System of Great Britain and Ireland.

OFFICIAL statistics of Prussian universities and technical colleges for the summer semester of 1925 show a total of 39,134 matriculated students, including 3234 students from other countries. To these figures may be added the numbers of students in commercial, agricultural, and veterinary colleges, which bring the total up to 42,744, including 3607 from other countries. Of these students from abroad, 1232 were German as regards their mother-tongue, and more than half of them (2110) were enrolled in the University of Berlin (1042) and the Berlin Technische Hochschule (795), Handels-Hochschule (169), Landwirtschaftliche Hochschule (82), and Tierarztliche Hochschule (22). Bulgarian (246), Russian (191), Norwegian (108), and Chinese (101) students were specially numerous in the universities; Bulgarian (158), Russian (140), and Roumanian (134) in the technical colleges. English students in the University of Berlin numbered 10. None of these figures include 'Hörer' or unmatriculated students. The University of Berlin provides through its Deutsche Institut für Ausländer a continuous series of courses in German language, literature, and institutions, each lasting two months. The thirty-eighth of the series (December 1925-January 1926) was attended by 130 students belonging to thirty-two nationalities and including 40 Russians, 17 Japanese and Koreans, 12 Chinese, and 6 Jugo-slavs.

Contemporary Birthdays.

March 13, 1873. Dr. Charles S. Myers, C.B.E., F.R.S.
March 14, 1879. Prof. A. Einstein, For. Mem. R.S.
March 15, 1855. Mr. Charles Vernon Boys, F.R.S.
March 16, 1846. Prof. Gosta Mittag-Leffler, For. Mem. R.S.
March 17, 1863. Sir Herbert Jackson, K.B.E., F.R.S.
March 17, 1847. Sir Alexander B. W. Kennedy, F.R.S.
March 19, 1871. Prof. William Arthur Bone, F.R.S.

Prof. EINSTEIN was born at Ulm (Donau). Nobel laureate in 1921, he was Copley medallist of the Royal Society last year, and recently was awarded the Royal Astronomical Society's gold medal. He is best known, indeed almost popularly known, as the originator of the theory of relativity. In 1905 he showed that the time and space we measure are local in meaning and that we have no means of determining absolute space and time. Then came the identification of mass with energy. In 1915 the earlier theory was extended by a noteworthy generalisation bringing gravity into the scheme. The three crucial astronomical tests of Einstein's general theory of relativity have now all been verified and the theory has even been used to confirm the suspected high density of the white dwarf stars. Einstein has also been concerned in the development of the quantum theory. In 1905 he put forward his law of the photoelectric effect and further contributions on the theory of ionisation and the specific heats of solids culminated in 1917 in another fundamental result—a general equation connecting absorption and emission coefficients.

Mr. C. V. BOYS was born at Wing, Rutland. He was educated at Marlborough and the Royal School of Mines. In 1896 the Royal Society allotted him a Royal medal for the introduction into physical research of refined measurement methods by the use of drawn quartz fibres. Recognition was again accorded by the Society in 1924, when Mr. Boys was awarded the Rumford medal for his invention of the gas calorimeter.

Sir HERBERT JACKSON, Director of Research, British Scientific Instrument Research Association, was formerly Daniell professor of chemistry, University of London, King's College. President of the Rontgen Society, 1901–3, he was president of the Institute of Chemistry, 1918–21. In 1919 he delivered the Trueman Wood lecture at the Royal Society of Arts on "Glass and some of its Problems." Sir Herbert made recently the statement that it is not possible at the present day to obtain anywhere optical glass and optical instruments better than, or in many cases, as good as, those manufactured in Great Britain.

Sir ALEXANDER KENNEDY, consulting engineer, was born at Stepney and educated at the City of London School and the Royal School of Mines. Professor of engineering in University College, London, 1874–89, he there originated the first of the engineering laboratories which now form an essential part of the scientific training in engineering at universities and colleges.

Prof. BONE, chemical and fuel technology engineer, was born at Stockton-on-Tees. Educated at the Friends' School, Ackworth, Stockton Grammar School, and the Leys School, Cambridge he graduated at the Victoria University, Manchester, proceeding afterwards to Heidelberg University, studying there under the late Prof. Victor Meyer. In 1910 the leaders of the coal-gas industry endowed a special chair at the University of Leeds in memory of the late Sir George Livesey, and Prof. Bone was its first occupant. He is the inventor of the 'Bonecourt' system of incandescent surface combustion.

Societies and Academies.

LONDON.

Royal Anthropological Institute (Indian Section), February 23.—**R. E. Enthoven**: Ethnographic research in India. Dealing with the systematic survey of the larger provinces inaugurated by Risley after the census of 1901, the various theories of caste origin were noted, and its present characteristics explained. Stress was laid on the importance of a more thorough record of exogamous caste and tribe divisions, particularly in connexion with the primitive type having many of the aspects of totemism. Further and more extensive work of the nature of recent anthropometrical observations in India is necessary. For the immediate future, the compilation of an all-India record of tribes and castes, and the limitation of the scope of inquiry in regard to both social structure and primitive custom to the already existing questionnaires drawn up by experts are desirable.

Optical Society, February 25.—**O. Aves**: Notes on the significance and detection of low errors of refraction. Examination of a great number of records of tests on the eye for the purpose of prescribing spectacles reveals a large proportion of low errors of refraction. Certain modifications of the usual technique should be incorporated when testing such cases. The usual objective methods of sight examination prior to a subjective test are practically useless in the estimation of errors less than one dioptre; they produce distinct after-images on and around the macular area, which perceptibly interfere with vision. In the subjective test the lenses should be added binocularly, before testing the eyes separately. The blocking of one eye tends to induce strain. Change of lenses during a test should be made smoothly without allowing the eyes to be uncovered by a lens or to be covered by two lenses. Other points in the testing of small errors are the strength of the spherical and cylindrical lens elements, the direction of the axis of the cylinder, refinement of the test for muscular correction, and the possibility of the presence of irregular astigmatism.—**W. H. A. Fincham**: Vertex power and its measurement. The demand for increased accuracy in the determination of refractive errors has emphasised the need for accurate specification and measurement of the powers of correcting lenses. The effect of an ophthalmic lens may be expressed in a number of different ways. The following quantities are used: (1) Equivalent or true power; (2) vertex power or vertex refraction, *i.e.* the power at the vertex nearer the eye; (3) neutralising power, usually the front vertex power; (4) thin lens power, *i.e.* the sum of the powers of the two surfaces, thickness being neglected. In the case of ophthalmic lenses, vertex power is the important quantity, as it gives the effective value of the lens at some definite and easily determined point on the lens, and consequently lenses of any form having the same vertex power are interchangeable if the vertex of each lens occupies the same position with respect to the eye.

CAMBRIDGE.

Philosophical Society, February 1.—**F. G. Mann** and **Sir W. J. Pope**: Metallic complexes with aliphatic poly-amines. The preparation and configuration of complex compounds of platinum, palladium, rhodium, cobalt and nickel with $\alpha\beta\gamma$ triaminopropane, $\beta\beta'\beta''$ triaminotriethylamine, and $\gamma\gamma'\gamma''$ triaminotripropylamine is described.—**R. T. M. Haines** and **Sir W. J. Pope**: Isoquinoline and the isoquinoline reds. By fractional precipitation of coal-tar quinoline, the amount of isoquinoline present was shown to be nearly 5·5 per cent., or six times as much as was supposed. The reaction leading to the production of isoquinoline red and its homologues is a delicate test for the presence of a reactive methyl-group such as exists in quinaldine. Anhydrous ferric chloride and stannic chloride are as efficient condensing agents as aluminium chloride.—F. H. **Constable**: The behaviour of the centres of activity of saturated surfaces during the initial stages of unimolecular reaction. While decrease in pressure of the reactant has little effect on the velocity of reaction at saturated surfaces, chemically inert diluents cause a marked decrease. These results confirm that the molecules do not react at the instant they bombard the surface, but during the period they remain absorbed. An extension of the Langmuir-Frenkel theory to the dynamics of adsorption on the centres of activity accounts quantitatively for the facts.—A. J. **Berry**: Direct titration of thallous salts by potassium iodate. Thallous salts are capable of quantitative oxidation to the thallic condition by potassium iodate in the presence of a high concentration of hydrochloric acid. Iodine liberated during the reaction is oxidised to iodine monochloride, hydrolysis of the latter being suppressed by the high concentration of hydrochloric acid present.—R. G. W. **Norrish**: influence of surfaces on the combination of ethylene with the halogens. The suspension of reactivity resulting from the drastic drying of potentially reactant systems is rather to be ascribed to a drying of the apparatus, than to any ultra-dryness of the reactants. For example, if the bimolecular velocity coefficient or the surface reaction between ethylene and chlorine in glass vessels be represented by unity, then in similar paraffin wax vessels it falls to 0·0008, even if the gases are moist. When the glass vessels are baked out under a high vacuum, the velocity coefficient falls to 0·12 in spite of the fact that a small portion of the vessel remains of necessity undried. Since the whole of the reaction occurs via the adsorbed surface film, these results indicate that only sufficient water is necessary for full reaction as will saturate the surface with (probably) a unimolecular layer; thus though present only in very small quantities, water may still enter stochiometrically into the reaction equation. —W. A. **Waters**: The chlorination and bromination of 4-aminodiphenyl.—**Miss M. Wright**: Oxidation at charcoal surfaces. Sugar charcoal brings about the oxidation of oxalic acid in dilute solutions, and is itself slowly oxidised. Fractional poisoning experiments show that the two processes are independent, and occur on different parts of the charcoal surface. On blood charcoal there are two catalytically active areas, one small, highly active area containing iron, which is preferentially poisoned by potassium cyanide; and another larger, less active area, similar to that on sugar charcoal. Iron-containing charcoals have been prepared free from nitrogen; when these are reduced in hydrogen, they contain two catalytic surfaces, similar to those of blood charcoal. Nitrogenous charcoals are very active, owing to their large specific surface.

MANCHESTER.

Literary and Philosophical Society, February 9.—R. A. **Wardle**: Rain cotton in the Sudan. The southern Sudan is not an ideal area for cotton grown under rainfall conditions owing to the shortness of the rainy season and to the uncertain distribution of the annual rainfall. Indigenous short staple cottons have been grown, however, for at least eighty years, and experiments have shown that American long staple varieties can be grown successfully and will produce cotton sufficient in quality and quantity to warrant the establishment of cotton cultivation in the Central and Southern Provinces, thus enabling these areas to obtain a surplus of income over expenditure available for developmental schemes. The Government policy is to encourage the cultivation of American long staple varieties by issuing free seed and by providing marketing and ginning facilities. The ultimate limit of acreage under rain cotton will depend largely upon the extent to which road and rail communication between districts and ginneries can be developed.—W. E. **Alkins**: The influence of the metallic contact between the component wires upon the electrical resistance of a stranded conductor. The resistance of a stranded conductor composed of bare wires is usually calculated upon the assumption that the component wires behave in respect of the transport of electrons as though they were insulated from each other. This assumption has been tested experimentally in the case of a conductor consisting of seven copper wires. It was found that the resistance of the stranded conductor was equal, within the limits of experimental error, to that calculated by means of the Reciprocal Law from the resistances of the component wires, and that the metallic contact between the individual wires was therefore without appreciable influence.

PARIS.

Academy of Sciences, February 8.—Emile **Haug**: Fossils of the middle Lias collected by the Charcot expedition at Cape Stewart (Jameson's Land, East Greenland). The fossils found are characteristic of the middle Lias. This view is not in agreement with the results of B. Lundgren (Danish expedition 1891–92).—Georges **Claude**: The explosion at Boulogne-sur-Seine. An account of a fatal explosion of a liquid air plant, and a discussion of the possible causes of the accident.—Ch. **Depéret**: Excavations for prehistoric remains in the layer in which the fossil men of Denise (near Puy-en-Velay) were found.—C. **Sauvageau**: A new type of alternation of generations in the brown algæ.—André **Bloch**: Some theorems on the integral and meromorph functions of a variable.—Kyrille **Popoff**: The gaps which may be presented by a Taylor's series representing a regular analytical function at infinity, and only admitting one singular point which is an essential singular point.—Eugène **Barré**: The theory of [military] mine explosions.—Léon **Brillouin**: Rotation spectra, in the new quantum mechanics, with calculation of the matrices.—André **Pignot**: The adiabatic ignition of hydrocarbon mixtures. The method adopted was the determination of the initial temperature necessary to obtain ignition with a fixed volume compression. The hydrocarbons chosen were those present in ordinary petrol. Experiments were also made with alcohol.—René **Lucas**: The rotatory power of camphor. The hypothesis that camphor can exist in two molecular forms possessing different rotatory powers and dispersions, and that the proportion of these two forms varies from one solvent to another, is in agreement with the experimental results given in this and in an earlier communication.—Mlles. Ellen **Gleditsch** and C. **Chamié**: Contribution to the study of 2-mesothorium and of actinium: These experiments confirm and complete the work of Yovanovitch: the chemical reactions of mesothorium-2 resemble those of the cerium earths, more especially lanthanum.—Albert **Portevin** and François **Le Chatelier**: Some physical properties of the ultra light magnesium alloys. Determinations of specific volume, electrical resistance and coefficient of expansion of magnesium alloys. The most interesting types from the point of view of practical utility are the binary alloys with nickel or copper, and the ternary alloys magnesium-aluminium-nickel and magnesium-aluminium-copper —A. **Lassieur** . The magnesia carried down by aluminium hydroxide If to a solution containing aluminium and magnesium only just sufficient ammonia is added to precipitate the alumina (pH = 7) no magnesia is precipitated. With increasing quantities of ammonia, there is increased precipitation of the magnesia —L. **Blanc** and G. **Chaudron** : Study of the transformation and oxidation of chromium sesquioxide —André **Kling** and Daniel **Florentin** · The hydrogenation of organic substances realised at a high temperature and under high pressure. The temperatures at which hydrogenation commences were determined for various organic compounds, and these coincided with the temperatures at which decomposition commenced. It is concluded that in hydrogenation at high temperatures and pressures it is molecular hydrogen which acts on nascent organic molecules —**Tiffeneau** and Mlle. J. **Levy** . The isomerisation of the ethylene oxides and comparison of the affinity capacities of some cyclic and acyclic radicals —Marcel **Godchot** and Pierre **Bedos** . The stereoisomeric *o*-methyl-cyclopentanols —Louis **Barrabé** The mode of formation and the age of the eruptive rocks of the middle region of the Sakalave country (west of Madagascar).—P **Fallot** and R **Bataller** : The direction and age of the folds in the mountains of Bas-Aragon and Maestrazgo (Spain) —L. **Lavauden** and M **Solignac** . Some geological results of the Trans-saharan expedition of Colonel Courtot (1925).—A. **Demay** · The Hercynian tectonic of Maures —Ch. **Lormand** : Chemical analysis of the Capvern (Hautes-Pyrénées) mineral water —J **Thoulet** : Submarine volcanism at great depths . A **Renier** · The general morphology of Ulodendron —Ch. **Brioux** and J. **Pien** . The comparative fertilising action of the different forms of nitrogen existing in the new ureic nitrogenous manures derived from cyanamide Results with experimental cultures containing ammonium sulphate, guanylurea sulphate, or dicyandiamide, with special reference to the effect on nitrification —**Doyon** and I. **Vial** : The isolation of an extremely active anti-coagulating substance free from phosphorus by the prolonged autolysis of organs and acid alcohol.—Emile F. **Terroine** and Mlle Anne Marie **Mendler** . The influence of the nature of the ternary foods on the amount of nitrogen retention in the course of growth.—J. **Cristol**, L **Hedon**, and A **Puech** . The passage of the digestive polypeptides into the portal circulation and their arrest in the liver. Details of experiments proving that polypeptides pass into the portal vein in the course of digestion, and are arrested by the liver, since they are not found in the arterial blood —A. **Policard** and M. **Boucharlat** The mechanism of the characters of the plasma of sarcomatous animals making it suitable for a medium for the culture of tissues

CALCUTTA.

Asiatic Society of Bengal, January 4 —P. C. **Mahalanobis** : Analysis of race-mixture in Bengal. Measurements of 200 individuals of Anglo-Indians (new style) in Calcutta are compared with 30 typical castes of North India, representing about 6 geographical divisions and 4 or 5 cultural strata. Intermingling has not been chaotic ; it presents a gradual and well-ordered character in which cultural affinity and cultural selection have played a very important part.—MM. Haraprasad **Shastri** : Bhadra Yāna There has been a gradual increase of number of yānas known Yāna = a school of thought, modern Indian "panth" The yāna was founded by Bhadrapāda. The central teaching is the negation of the citta —Johan van **Manen** : The Pali Text Society's Pali-English Dictionary.

ROME.

Royal Academy of the Lincei, December 20 —Francesco **Severi** : Constant level curves of Picard's integrals —O. M. **Corbino** · Thermo-electric power and Hall's effect.—Michele **Cantone** . New method of studying experimental results It is often useful, in addition to the curve showing the variation of any phenomenon with a particular property, to trace the curve showing the relation between the corresponding increments.—Achille **Russo** : The first accessory conjugation between impure gametes in *Cryptochilum echini* Maupas.—Beniamino **Segre** : A property of symmetrical determinants of the sixth order.—Carlo **Severini** : Convergence of the series of orthogonal functions.—Giovanni **Sansone** : Indeterminate equations of unity of negative type in real quadratic bodies. The case $D = 2p$, with p prime.—G. **Wataghin** : Dependence of the velocity of light on the movement of the source.—E. **Billows** : Crystals of sulphur accompanying the anglesite and galena of Monteponi. —Helios **Scaetta** . Partial hermaphroditism and parthenocarpia in *Phœnix dactylifera* L.

VIENNA.

Academy of Sciences, January 14.—O. **Wettstein** : A new lizard of the genus Enyalius from Ecuador. Specimens are in the Vienna Natural History Museum. —A. **Duschek** : The relative theory of surfaces.—F. **Holzl** Organic acids and bases in non-aqueous solutions —E **Heinricher** . Is the formation of haustoria in Santalaceæ produced by chemical stimulation or by contact ?—Fr. **Hlucka** : Comparison between the dispersion formulæ of the atomic theory and of the continuity theory —A. **Köhler** · Report on the progress of the petrographic-geological researches in the south-western Waldviertel (Lower Austria) —H **Handel-Mazzetti** : Plantæ novæ Sinenses (xxxix.)

WASHINGTON, D C.

National Academy of Science (Proc Vol 12, No 1, January).—Ernest W **Brown** . The effect of varying mass on a binary system . a correction [to a paper in the May issue of the *Proceedings*].—Charles E. **Allen** : The direct results of Mendelian segregation If it is possible to recognise the four spores formed by division of a single mother cell, some indication of the effects of chromosome segregation can be expected in the haploid plants developing from the spores Generally each tetrad of spores contains two types of spore only as regards the two characters examined in *Sphærocarpos Donnellii* , tetrads with the possible four different spores formed a small minority —John **Belling** and A F. **Blakeslee** On the attachment of non-homologous chromosomes at the reduction division in certain 25-chromosome daturas —M **Demerec** . Reddish—a frequently 'mutating' character in *Drosophila virilis*. 'Reddish' is a body colour characteristic which seems to be an allelomorph of yellow and mutating frequently to wild type —W. E **Castle** . The explanation of hybrid vigour Recent evidence supports the heterosis (or heterozygosis) theory that the vigour of hybrids arises from the fact that they are heterozygous for all genetic factors in which the parents differed This leads to an acceleration of all metabolic processes in hybrids.—Gregory Paul **Baxter** and Howard Warner **Starkweather** . The density and atomic weight of helium (ii.). 2-litre globes were used instead of 1-litre (NATURE, July 11, 1925, p. 68). Original values obtained when corrected give the density as 0·17846. The average density at a pressure of half an atmosphere is exactly one-half that at a pressure of one atmosphere. The density of oxygen being 1·42898, the atomic weight is very close to 4·000.—**Gilbert N. Lewis**: The nature of light (see NATURE, February 13, p. 236).—**Ernest Orlando Lawrence**. The rôle of the Faraday cylinder in the measurement of electron currents. For electrons under accelerating voltages up to about 24 volts there is a regular increase of electron current to the Faraday cylinder, with increase of length of the latter. With accelerating voltages of 20 to 100 volts, secondary electrons generated by impact in the cylinder lead to large variations in the electron current measured.—**Linus Pauling**: The quantum theory of the dielectric constant of hydrogen chloride and similar gases. The electric moment of the molecule in hydrogen chloride is that of a dipole with proton and electron 0·0694 Å.U. apart; for hydrogen bromide the distance is 0·0528 Å.U.—**L. B. Loeb**: (1) The mobility of gaseous ions in HCl gas and HCl air mixtures. In pure dry hydrogen chloride gas, the average mobilities of the positive and negative ions at 20° C. and 760 mm. mercury pressure are 0·65 cm./sec. per volt/cm. and 0·56 cm./sec. per volt/cm. In mixtures with air there is evidence of the formation of labile clusters formed by increased concentration of molecules of one type in the neighbourhood of the ion. (2) The mobility of gas ions in HCl mixtures and the nature of the ion. Assuming an inverse fifth power law, it is calculated that the molecules of higher dielectric constant in a mixture are present in far greater numbers in the immediate neighbourhood of the ion than in the rest of the gas. This would account for the labile clusters evidence for which was found above. The nucleus plays an exceedingly minor rôle in determining values of ionic mobility.—**R. A. Millikan**: High-frequency rays of cosmic origin (see NATURE, December 5, 1925, p. 823).—**J. R. Roebuck**: The Joule-Thomson effect in air. The porous plug used consisted of a porcelain tube with a rounded end, and great precautions were taken to ensure that the inlet pressure was maintained constant. Inlet pressure of 30 to 220 atmospheres and temperatures of 25° to 300° C. were used. The Joule-Thomson effect falls steadily with rising temperature and pressure, passes through zero, and becomes negative. The coefficient of expansion at constant pressure increases with both temperature and pressure but at a decreasing rate. The temperature of the ice-point works out as 273°·15 K.—**Joseph Miller Thomas**: On normal co-ordinates in the geometry of paths.—**E. B. Stouffer**: A simple derivation of Kronecker's relation among the minors of a symmetric determinant.

Diary of Societies.

SATURDAY, MARCH 13.

ROYAL SANITARY INSTITUTE (at Town Hall, Hastings), at 10.30 A.M.—Dr. G. R. Bruce, Miss Hester Viney, Dr. J. Fenton, and others: Discussion on Mothercraft and Fathercraft.—J. Parkin, H. T. Taylor, and others: Discussion on The Effect of the Public Health Act of 1925 on the Work of Municipal Engineers and Sanitary Inspectors.

BIOCHEMICAL SOCIETY (at University College), at 2.15.—C. R. Harington: Chemistry of Thyroxin—(a) Method of Isolation from the Thyroid Gland; (b) Constitution and Synthesis of Iodine-free Thyroxin.—H. J. Channon: Some Experiments on the Biological Significance of Squalene (Spinacene).—H. J. Channon and G. F. Marrian: An Unidentified, Unsaturated Hydrocarbon occurring in Mammalian Liver.—Prof. I. M. Heilbron: The Chemical Nature of Squalene (Spinacene).—F. H. Carr and E. A. Price: Colour Reactions attributed to Vitamin A.—H. Jephcott and A. L. Bacharach: Studies in the Vitamins of Cod Liver Oil. Part I.—Prof. H. S. Raper: The Production of 3.4 Dihydroxy-phenylalanine from Tyrosine by the Action of Tyrosinase.—R. K. Cannan, Dr. P. Haas, and T. G. Hill: Oxidation-Reduction Potential of Hermidin (Chromogen of *Mercurialis perennis*).—Dr. C. Dorée and E. C. Barton-Wright: A Note on the Stone-Cells of the Pear.—Margaret H. O'Dwyer: On the Nature of the Hemicelluloses.—H. D. Carey: The Relation between Hydrogen Sulphide, Hyposulphites, and Thiosulphates; by a New Method of Structural Formulæ.—E. Ponder: The Shape of the Erythrocyte and its Respiratory Function.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (2).

British Psychological Society (at University College), at 8.—Dr. Eliza A. Collie: The Upper Limits of the Growth of Intelligence.—S. J. F. Philpott: Some Further Notes on Work Curves.

Institute of Transport (North-Eastern Local Section) (at Town Hall, Newcastle-upon-Tyne), at 3.—Prof. J. H. Jones: State Ownership of Waterways.

Scottish Junior Gas Association (at Royal Technical College, Glasgow), at 7.—S. H. Hunter: Scientific Service.

MONDAY, March 15.

Institution of Post Office Electrical Engineers (at Royal Technical College, Glasgow), at 2.30.—Capt. Hill: The Engineering Aspect of Telephone Exchange Accommodation.

Cambridge Philosophical Society (Special Meeting) (in Cavendish Laboratory), at 4.30.—Prof. A. Sommerfeld: Some Controversial Points in the Theory of Spectra (Lecture, in English).

Victoria Institute (at Central Buildings), at 4.30.—Rev. Canon V. F. Storr: Revelation.

Royal Geographical Society (at Lowther Lodge), at 5.

Royal College of Surgeons of England, at 5.—Mr. Shattock: Demonstration of Specimens of Some Bone Tumours.

Institution of Electrical Engineers (Mersey and North Wales (Liverpool) Centre) (at Liverpool University), at 7.—J. E. Allan, A. G. Barnard, and others: Discussion on Electricity on Board Ships.

Institution of Electrical Engineers (North-Eastern Centre) (at Sopwith's Lounge, Newcastle-on-Tyne), at 7.—Informal Discussion on Power Station Economics.

Institution of Electrical Engineers (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.15.—R. B. Matthews: Electro-Farming; or the Application of Electricity to Agriculture.

Institution of Automobile Engineers (Scottish Centre) (at Royal Technical College, Glasgow), at 7.30.—Dr. W. R. Ormandy: The Production of Oil.

Royal Institute of British Architects, at 8.

Royal Society of Arts, at 8.—W. F. Higgins: Thermometry (Cantor Lectures) (1).

Medical Society of London, at 9.—Dr. E. F. Buzzard: The Principles of Treatment in relation to Diseases of the Nervous System (Lettsomian Lectures) (3).

Chemical Industry Club.

TUESDAY, March 16.

Royal Irish Academy (at Dublin), at 4.15.

Royal College of Physicians of London, at 5.—Dr. B. Hart: The Development of Psycho-pathology and its Place in Medicine (Goulstonian Lectures) (2).

Royal Institution of Great Britain, at 5.15.—Prof. C. H. Desch: The Growth of Crystals (1).

Royal Statistical Society (at Royal Society of Arts), at 5.15.—Major P. Granville Edge: The Growth of Mortality due to Motor Vehicles in England and Wales, 1904–23.

Mineralogical Society (at Geological Society), at 5.30.—A. H. Hallimond: Molecular Volume Relations in the Mica Group.—E. D. Mountain: (*a*) Smithsonite from the Rhodesia Broken Hill Mines, (*b*) The Identity of the Cobija and Lampa Meteoric Stones.

Institution of Electrical Engineers (North-Western Centre) (at Engineers' Club, 17 Albert Square, Manchester), at 7.—L. C. Grant: Developments in High Power Fuses.

Royal Photographic Society (Scientific and Technical Group) (Annual Meeting), at 7.—W. B. Ferguson: Standardisation of the Measurements of Photographic Density.—T. Thorne Baker and W. A. Balmain: The Effect of Colour-Sensitiveness on the Gradation of a Photographic Plate.

Society of Chemical Industry (Birmingham and Midland Section) (Annual Meeting) (at Birmingham University), at 7.15.—Prof. A. R. Ling: Communications from the Department of the Bio-chemistry of Fermentation.

Institute of Metals (Sheffield Local Section) (at Sheffield University), at 7.30.—G. B. Brook: Aluminium: Where and How it is made.

North-East Coast Institution of Engineers and Shipbuilders (Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—A. E. Mitchell: Heavy Timber Construction in Harbour and Dock Works.

Royal Anthropological Institute, at 8.15.—Dr. G. Landtman: Some Agricultural Rites of the Kiwai Papuans.

British Institute of Philosophical Studies (at Royal Society of Arts), at 8.15.—Prof. S. Alexander: Artistic and Cosmic Creation (Lecture).

Royal Society of Medicine (Pathology Section) (Annual Meeting), at 8.30.

WEDNESDAY, March 17.

Institution of Civil Engineers (Students' Meeting), at 6.—J. G. Kimber: The Production of Gaseous Fuel.

Institution of Electrical Engineers (Sheffield Sub-Centre) (at Sheffield University), at 7.30.—S. Evershed: Permanent Magnets in Theory and Practice (Second Paper).

Royal Meteorological Society, at 7.30.—Prof. S. Chapman: Some Recent Advances in Atmospheric Physics (G. J. Symons Memorial Lecture).

Royal Society of Arts, at 8.—Lieut.-Col. J. H. Borastan: Co-Partnership.

C.B.C. Society for Constructive Birth Control and Racial Progress (at Essex Hall, Strand), at 8.—E. J. Ledbetter: Social Inadequacy and the Size of the Family (Lecture).

Institution of Structural Engineers (jointly with the British Section of the Society of Civil Engineers of France), at 8.—A. Knappen: Notes on the Restoration of the Palace of Versailles and the Trianon.

Institute of Chemistry (London Section).

Society of Glass Technology (at Stourbridge).

THURSDAY, March 18.

Royal Society, at 4.30.—Prof. S. Chapman, J. Topping, and J. Morrall: On the Electrostatic Potential Energy, and the Rhombohedral Angle, of Carbonate and Nitrate Crystals of the Calcite Type.—Prof. A. O. Rankine: The Effect of Temperature on the Viscosity of Air.—G. I. Finch and L. G. Cowen: Gaseous Combustion in Electric Discharges. Part I.—C. N. Hinshelwood and W. K. Hutchison: A Homogeneous Unimolecular Reaction—the Thermal Decomposition of Acetone in the Gaseous State.—*To be read in title only*:—Prof. H. Lamb: On Wave Resistance.—C. B. Eddy and A. H. Turner: The L Emission Series of Mercury.—G. R. Goldsbrough: The Properties of Torsional Vibrations.—E. T. Hanson: The Theory of Ship Waves.

Royal College of Physicians of London, at 5.—Dr. B. Hart: The Development of Psycho-pathology and its Place in Medicine (Goulstonian Lectures) (3).

Linnean Society, at 5.—J. L. Sager: Phyllody of the Corolla in *Primula vulgaris* Huds.—Dr. R. T. Gunther: An Early MS. of Apuleius Barbarus c. 1100 A.D. in Facsimile.—G. P. Farran: The Copepoda Collected by H.M.S. *Research* in 1900.—Dr. Helena Bandulska: The Cuticles of Some Fossil and Recent Lauraceae.

Royal Institution of Great Britain, at 5.15.—Prof. J. Holland Rose: The Indecisiveness of Modern Warfare (1).

Institution of Mining and Metallurgy (at Geological Society), at 5.30.

Child-Study Society (at Royal Sanitary Institute), at 6.—Miss C. von Wyss: Spiders as a Nature Study Topic.

Institution of Electrical Engineers, at 6.—L. C. Grant: Developments in High-Power Fusible Cut-Outs.

Society of Chemical Industry (Birmingham and Midland Section) (at Chamber of Commerce, Birmingham), at 7.15.—Prof. W. A. Bone: Some Recent Advances in our Knowledge of Gaseous Combustion.

Institute of Metals (London Local Section) (at Institute of Marine Engineers), at 7.30.—Dr. C. J. Smithells: The Preparation and Structure of Wires of Pure Tungsten.

Chemical Society, at 8.—R. J. W. Le Fèvre and E. E. Turner: Orientation Effects in the Diphenyl Series. Part II. The Constitution of Bandrowski's Dinitrobenzidine.—H. R. Ing and R. Robinson: The Orientating Effect of Free and Bound Ionic Charges on Attached Simple and Conjugated Unsaturated Systems. Part I. The Nitration of some Benzylamine Derivatives.—R. S. Cahn and R. Robinson: The Morphine Group. Part IV. A New Oxidation Product of Codeine.

Royal Society of Tropical Medicine and Hygiene (Laboratory Meeting) (at Royal Army Medical College, Grosvenor Road, S.W.), at 8.15.—Demonstrations by: Prof. Warrington Yorke (on behalf of Prof. Blacklock), Dr. P. A. Buxton, Col. Clayton Lane, Col. W. P. MacArthur, Dr. A. C. Stevenson, Dr. J. G. Thomson and Dr. A. Robertson, Dr. C. M. Wenyon and Dr. H. H. Scott.

FRIDAY, March 19.

Institution of Municipal and County Engineers (North-Western District Meeting) (at Victoria Hotel, Deansgate, Manchester), at 2.30.—Sir Lewis Beard: New Legislation affecting Local Authorities, including the Public Health Act, 1925, and the Roads Improvement Act, 1925.

Institute of Hygiene, at 3.30.—Dr. R. S. Stevenson: Affections of the Ear, Nose, and Throat and their Prevention.

Royal Society of Arts (Indian Section), at 4.30.—Lady Chatterjee: Women and Children in Indian Industries.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimens of Hydrocephaly and Encephalocele.

Society of Chemical Industry (Liverpool Section, jointly with Manchester Section) (at Liverpool University), at 6.—Prof. T. P. Hilditch: Structural Chemistry of the Higher Fatty Acids.

Institution of Mechanical Engineers, at 6.—A. E. L. Chorlton: The High Efficiency Oil-Engine.

Institution of Structural Engineers (Yorkshire Branch) (at Great Northern Hotel, Leeds), at 6.30.—C. A. Harding: Some Preliminary Factors affecting the Design of Industrial Buildings.

Royal Photographic Society, at 7.—H. Bairstow: Photography as a Medium of Art Expression.

Photomicrographic Society (at 4 Fetter Lane), at 7.—Members' Evening.

Society of Chemical Industry (South Wales Section) (Annual General Meeting) (at Swansea Technical College), at 7.30.—C. A. Seyler: Chairman's Address.

Junior Institution of Engineers, at 7.30.—G. H. Willett: Pipe Work: Its Manufacture and Layout.

Royal Institution of Great Britain, at 9.—J. Tweed: Chips from a Sculptor's Note-Book.

SATURDAY, March 20.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (3).

Physiological Society (at University College).

British Mycological Society (at Lister Institute).

PUBLIC LECTURES.

SATURDAY, March 13.

Horniman Museum (Forest Hill), at 3.30.—Dr. H. G. Cannon: How Animals Feed and what they Eat.

MONDAY, March 15.

St. Thomas's Hospital, at 5.—Prof. R. H. A. Plimmer: The Importance of Vitamins. (Succeeding Lecture on March 16.)

SATURDAY, March 20.

Horniman Museum (Forest Hill), at 3.30.—C. Daryll Forde: Agriculture and the Origin of Civilisation.

SATURDAY, MARCH 20, 1926.

The Coal-mining Industry in Great Britain.

THIS eagerly expected Report of the Coal Commission, which was issued on March 11, constitutes a document of the highest interest and importance (H.M.S.O.; 1*s.* net). The Commissioners evidently have been impressed by the gravity of the situation and the magnitude of the task entrusted to them, and have spared no pains in making a complete investigation of the questions involved.

It may be said at once that, as might be expected from the exceptional qualifications of the Commissioners, the report is an eminently sound and sane one, and the best evidence of this lies in the fact that it has impartially dissatisfied all parties to the dispute. It is too often forgotten that there are at least three parties concerned, namely, the miners, the mine-owners, and the general public: the first two are articulate, not to say vociferous; the third is so inarticulate that its interest, vital though it is, is too frequently overlooked. It is sincerely to be wished, though the hope is scarcely likely to be realised, that the public would bestir itself sufficiently to read this report and would for once find a means of expressing its views.

It is obviously impossible to discuss in detail so voluminous a report; only a few of the main recommendations can here be considered. Perhaps the recommendation which will impress most people is that coal royalties shall be acquired by the State by purchase from their present owners. There is no fault at all to find with the principle of State ownership of minerals; as a matter of fact the greater portion of the minerals in the world are owned by the States within the territories of which they lie and are granted to mine-workers in the form of concessions. The most striking exceptions to this general method are to be found in Great Britain and the United States, where the minerals are the property of individuals or have been acquired by them. Incidentally it may be noted that these are the two countries in which mining has made the most progress and in which the wages of miners are the highest; this fact may be only a coincidence, or it may possibly be more deeply rooted than we are able to see at present in the condition of private ownership of the minerals.

The Commissioners amply justify the position that royalties are a perfectly legal form of ownership, and that if the State desires to acquire them it will have to pay for them. Their reasons are set out in the historical account which they give of royalties, but they by no means present the case in its entirety, because it is in fact much stronger than the report would lead the reader to believe; the opinion of the Commissioners that the State should now repair the error which it made when it parted with these royalties would lead the reader to infer that the State had at one time possessed these coal royalties. Such, however, is far from being the case: the State, or rather the Crown, in the past repeatedly claimed the ownership of metalliferous minerals, but never at any time set up the slightest claim to an ownership of coals.

Ownership of land and all that pertains to land in England dates from the Norman Conquest, and it is significant that the Doomsday Book, though it mentions other mines, never once mentions a coal mine, so that it may fairly be inferred that at the date of the Conquest no coal mines existed in England. The earliest document concerning coal mines of which we have any knowledge is a Scotch deed dated 1202, in which the superior granted a lease of certain collieries in Newbattle, and even at this period the absolute right of the land-owner to dispose freely of his coal appears to have been unquestioned, and has remained so until the present day. As stated by the Commissioners, the Great Case of Mines settled the rights of the land-owner to mines within his land, as has been very clearly set forth by Sir John Pettus in his *Fodinæ Regales*, published in 1670. Apparently the first mention of coal mines in legislation appears to have been in the well-known Statute of Elizabeth in 1601, which instituted the Poor Rate and empowered the overseers of the poor to levy such rate upon any occupier of lands, houses, *coal mines*, etc. It is highly significant that this Act excludes other mines from the operation of the Poor Rate, and assimilates coal mines to houses and other appurtenances of the land. In England, therefore, the State never parted with the ownership of coal mines, for the simple reason that it never owned them, and it is obvious that if it now wishes to acquire them, it can only do so by purchase. The Commissioners suggest that a purchase price of 100,000,000*l*. would be a fair equivalent; this price is only sufficient if royalty owners consent to accept a lower income than they are at present receiving on condition that it shall be in a more secure form, and the suggestion is not an unreasonable one.

Whilst the principle of State acquisition of royalties is clear enough, its execution bristles with difficulties, not a few of which the Commissioners, to do them justice, have foreseen and have endeavoured in part to meet. The principle which they propose, namely, that coal, the existence of which is not to-day proved, shall belong to the State, is a perfectly defensible one, though curiously enough they have missed the main argument in its favour. It is certain that such coal can only be discovered as the result of the exact knowledge of the geological structure of the country, which has been obtained by the labours of a public department, namely, the Geological Survey, to the maintenance of which every taxpayer has contributed. It is difficult to see why a Kentish farmer who has bought land purely for agricultural purposes should claim the ownership of the coal which happens to lie under that land, when he has contributed to the discovery of that coal nothing more than has an equally taxed person in any other part of the country.

The Commissioners have evidently realised, as every one who knows the industry must realise, that, if it is to survive, the cost of production must come down, and as two-thirds of this consists of wages, it is obviously here that the greatest economies are possible; of the alternatives, either of lowering wages or of increasing the hours of labour for the same wage, the Commissioners pronounce in favour of the former. It does seem, however, that they have not looked at the question of length of the working day from the proper point of view. Their main argument against increasing the length of the working day is that if it were so increased in Great Britain as to be brought up to the level of our principal competitors, these would immediately increase the length of their working day. Obviously the same argument might apply to a lowering of wages, but there is not a particle of evidence that anything of the kind would happen

Surely the proper way to approach the question of the length of a working day is to determine whether an increase of hours would unduly overtax the workers. Those who remember that, not so many years ago, the length of the working day was something like 50 per cent. more than it is to-day, and that men engaged in the even more arduous work of metal mining to-day work longer hours than coal miners, would unhesitatingly declare that the length of the coal miners' working day could be lengthened without inflicting the slightest hardship upon them. There is another alternative which never seems to have been placed before the Commissioners; even if it be suggested that a man who is hand-hewing in hard steam coal for six and a half hours has done as much physical work as can fairly be expected of him, the same cannot be said of the man whose work is running a coal-cutter, and it would appear to be a wise policy to have recommended that the hours of the men working in machine-cut faces should be lengthened. No doubt such a recommendation would present certain difficulties in practice, especially in mines where some districts are hand-cut and others machine-cut, but these difficulties would not appear to be insuperable. The recommendation would have the advantage of more nearly equalising the demands made upon the men, and it would encourage the more extensive use of machinery underground, because it would thus enable owners who put in machinery to get a better return on the capital thus invested.

It is rather surprising to find that in the chapter on profits, as indeed throughout the report, the wasting nature of the industry is nowhere recognised, and the fact is missed that it is necessary to make provision for the capital sunk in a colliery which must be replaced out of revenue before anything like a profit can be earned. The Commissioners estimate that to purchase the collieries of Great Britain would cost 350,000,000*l*.; as the annual output of the country may be averaged at 250,000,000 tons, this amounts to a capitalisation of 28*s*. per ton per annum. If it is assumed, as the Commissioners appear to suggest, that the average life of a colliery may be expected to be about forty years, it is not difficult to calculate what sinking fund would be required to replace the above capital. Assuming the interest on gilt-edged securities to be 4½ per cent., and that income-tax remains as at present 4*s*. in the *l*., the annual amount to replace the capital outlay would be as nearly as possible 4*d*. per ton, thus reducing the real profit from the figure of 1*s*. given by the Commissioners to 8*d*. Furthermore, the Treasury most unjustifiably charges income-tax on the aforesaid 4*d*., although, as just pointed out, it is not profit at all but merely a replacement of capital, so that the nominal profit of 1*s*. is thus cut down to 7*d*. Incidentally it may be suggested that if the Treasury were to refrain from collecting income-tax, which is strictly speaking a tax on profits, from that portion of the income of colliery owners which serves only to replace the capital sunk in the collieries, the nucleus of a fund could be formed which might help to tide the industry over difficult times.

Probably the most difficult point which the report discusses is the problem of what the industry is to do in May next. The Commissioners are quite clear on the point that the subsidy must not be renewed in any form whatever, and the figures which they present make their reason abundantly clear. It is shown that the subsidy has been employed to pay hewers at the high rate of 76*s.* per week on the average, or as much as 90*s.* per week in some districts, whilst it has enabled certain collieries to make quite handsome profits. It is clear enough that neither wages on so high a scale as this nor dividends to shareholders in collieries ought ever to be paid out of the pockets of taxpayers. It is, however, very difficult indeed to see how the industry is going to tide over the next few months without assistance of some kind, because the returns from the industry itself are not sufficient to pay what may be considered a reasonable wage to the lower paid men. The Commissioners, like all intelligent men, realise that the only wages which any industry can pay in the long run are the proceeds of the industry itself, although the Commissioners have not always expressed this clearly; for example, in discussing the policy of the subsidy, they speak of a gap " between the amounts that employers are willing to pay and the amounts that the workers are willing to accept "; it is not a question of what the employers are willing to pay but what they are able to pay; it cannot be too often repeated that the employers do not find the money wherewith to pay wages, they are merely the medium through which the money realised by the industry is handed over to the workers.

The Commissioners realise fully that if the various recommendations which they make are carried out, and if they have, as they well may have, the desired effect of re-establishing the industry, this will be a matter of time, and they do not indicate how the industry is to exist meanwhile. It is possible that some means might be found of tiding over the period of struggle which lies before the industry by an advance from the State, say on the joint guarantee of repayment by the Miners' Federation and the Mining Association, such advances to be used solely for keeping the wages of the lower paid men above subsistence level and not to pay high wages to the higher paid men or dividends to the colliery owners.

In any case, and whatever is done, all engaged in the coal industry must make up their minds to bear their share of the hardships which will have to be faced. As the Commissioners point out, the War has to be paid for, and they show " how impossible it is to insist that real wages shall in no case be below those ruling before the War." Men in the sheltered industries have been able to secure this unfair advantage, and have thus thrown an additional burden on those engaged in the competitive industries, and there seems no alternative but for the latter to shoulder it. Whilst in the words of the Commissioners in discussing the coal industry " the only generalisation about it that is safe is that no generalisation is possible," this much is certain: neither the Commissioners nor any one else can find any royal road by which the industry can be brought to the desired condition of prosperity, and the only avenue by which that goal may be reached for all engaged in the industry, whoever they may be, is hard work and privation.

H. LOUIS.

Egyptian Archæology.

(1) *The Mummy: a Handbook of Egyptian Funerary Archæology.* By Sir E. A. Wallis Budge. Second edition, revised and greatly enlarged. Pp. xxiv + 513 + 39 plates. (Cambridge: At the University Press, 1925.) 45*s.* net.

(2) *Egyptian Religion and Ethics.* By F. W. Read. Pp. viii + 152 + 6 plates. (London: Watts and Co., 1925.) 4*s.* 6*d.* net.

(1) WHILE Egypt has been fortunate in having a preservative climate and an industrious and artistic people who portrayed all its life, it has suffered by the rise of the Nile bed burying its early habitations under the ground. The prominence thus given to the tombs on the desert, as our main source of information, and the popularity of mummies, has led to a false idea of the importance of the funeral rites. This is further enforced when an encyclopædia of Egyptian usages, like the first volume under notice, is called " The Mummy," though that subject does not occupy a twentieth of its bulk. The greater part of the volume deals with the more interesting subjects of the history and language and the objects of utility; thus the living rather than the dead Egyptian is the object of this work.

A brief running account of the history of the kingdom occupies sixty pages on well-known lines, scarcely touching the long prehistoric ages. The list of principal kings' names in hieroglyphics further fills forty pages. A like space is given to a full recital of the stages in the decipherment of the method of writing, showing how far the different scholars carried it between Akerblad in 1802 and Hincks in 1848; this is illustrated by the finest photograph yet taken of the Rosetta stone. The principal hieroglyphs are listed in twenty-five pages, and rather more is given to a list of amulets and figures of gods, with some account of each. The description of usual tombs and their accessories fills the last hundred pages. Thus the stock subjects are pretty fully dealt with, in the form required by a general reader for reference, without entering on the detail needed by a student. A work of this scope is much needed, and no other single volume fills its place.

The great length and continuity of civilisation in Egypt renders it, perhaps, the most important country for studying the nature of man. It was in continual change, its fashions fluctuating around a norm which varied but slowly; yet it was often invaded by fresh peoples, who in mind and body always became assimilated to its culture, until the last two thousand years. This aspect is scarcely touched on in " The Mummy "; the distinctive changes in the history of the mirror, the head-rest, canopic jars, kohl pots, or beads, which serve as landmarks in archæology, are not noticed. The head-rest is said to support the neck, whereas it fitted close above the ear. Soap is said not to have been known early; but a cake of *suab* is figured along with a wash-basin in the IVth dynasty; the meaning of the name is 'causing to be clean,' and it may well be the origin of our *soap*. The red lip-salve is said not to have been found, but the little balls of soft pale rouge are known in the XIIth dynasty. The scarab beetle is said to be of one kind (p. 271), or of two kinds (p. 278), but five or six different genera are already known. The method of *cire perdue* casting is ignored. Thus a great opportunity has been lost of supplementing the knowledge of forty years ago which is here laid out, and the celebrated discoveries and the books of the last few years are not included. Some twenty slips in matters of fact also need correction.

The author expressly disclaims touching the subjects of art and architecture, and considers that they do not belong to the "professional Egyptologist . . . busy with his texts." To the Egyptian nature their art was, perhaps, more than their language as a national expression; they had a far higher and more complete mastery of form than of writing. To deal with Akhenaten—as here—without a word about his new naturalistic work, and its reflex on his ethics, is to miss the most pervading influence of that astonishing period. The sudden movement of thought was as if the Pre-Raphaelites had become the rulers of England with Comte to dictate the religion. The literature of the time could not express half of what the change would mean. We need to get away from the idea that words are needful to express thought; they are ambiguous, inadequate in scope, inexact in connexion. A good cartoon expresses more than a page of writing; it makes us think in things, and not in words. To write about a people it is needful to think as they did, to become one of themselves; in this Maspero succeeded better than any other writer.

(2) The smaller work by Mr. Read is a more detailed account of one section, the views on religion and ethics, and it claims to "depart widely from the views of recognised authorities." There does not seem to be anything fresh, however, in this account of the gods and the religious texts, and the work forms a convenient and readable introduction to the subject. The incessant formula which begins offering tablets, "An offering which the king gives," is discussed, without noting its social explanation. In primitive societies the chief is supported by food-rents from the estates, which he visits in turn. It would, then, be a gift from the king if he allowed this surplus to be devoted to the service of the dead. A further reason for keeping the formula would be that misappropriation of the offerings would be an offence against royalty. The list of sins is said not to have any principle to be traced in the order of it; but it has been shown to be grouped in fives of a similar nature, and this construction was probably to help memory by learning them on the fingers, like the ten commandments. Mr. Read has a considerable regard throughout for historical development, and treats the changes that are seen in the beliefs with the insight of modern writers, recognising that the Egyptians—like most other people—did not apply logic to the inconsistencies of different faiths.

FLINDERS PETRIE.

Agricultural England and Wales.

An Agricultural Atlas of England and Wales. Made on behalf of the Agricultural Economics Research Institute, University of Oxford. By J. Pryse Howell. (Published by Direction of the Ministry of Agriculture and Fisheries.) Pp. iv+26 maps. (London: H.M. Stationery Office; Southampton: Ordnance Survey Office, n.d.) 10*s*. net.

THIS atlas presents for England and Wales the agricultural statistics published in 1921 for Wales only. It follows the same plan as the earlier publication, except that a separate base map of the market-towns replaces the one on tracing-paper in the atlas of Wales. The new work has thus both the merits and defects of its predecessor, some of the defects being increased by the greater delay in publication.

The parish returns of agricultural statistics for June 1918, plotted in the first instance on maps of the scale 1 : 250,000, have been graphically represented by a quantitative 'dot' method on a scale of 1 : 1,500,000. The effect is to show at a glance the distribution of mountain and heath-land, permanent grass, and arable land, and also the principal crops and live-stock. The greatest value of the atlas lies in this statistical confirmation of general and regional impressions based hitherto only upon experience. Details of soil, relief, climate, and weather, so essential to the individual farmer, obviously cannot be shown, but a generalised soil map might have been prepared in place of, or in addition to, that showing solid geology. Much of northern and eastern England has surface soils of glacial and post-glacial origin, and in the chalk country much variety exists due to greater or less admixture of gravel or clay and flints.

It is unfortunate, too, that a winter census of live-stock could not be shown. In spring and autumn extensive movements of cattle take place. Not only is there the movement between mountain pastures and the valleys, but there is also the transference of stock in autumn to arable lands for fattening. The Midlands and the west supply beef cattle from June to December, the east from January to May. The summer census shows Norfolk as one of the counties with the least number of horned cattle and Leicester as one with the greatest. A winter census map would show a reversal of these positions. For general purposes, the greatest defects arise from the abnormal character of agriculture in 1918 and the changes which have taken place since. That year saw the maximum war effort in food production, and since then there has been a substantial decline both in the acreage of arable land and in certain crops. The general abnormality of 1918 may be seen by the following table:

	Arable Land (1000 Acres).	Wheat (1000 Acres)	Oats (1000 Acres).	Potatoes (1000 Acres).	Cows and Heifers in Milk or in Calf (1000).	Other Cattle (1000).	Ewes for Breeding (1000).	Other Sheep (1000).
1913 . .	11,058	1702	1975	442	2264	3453	6699	10,431
1918 . .	12,399	2557	2780	634	2578	3623	6487	9,988
1925 . .	10,682	1500	1868	493	2713	3450	6397	9,578
Av for 10 yrs, 1915–24 . .	11,503	1988	2237	509	2512	3429	6041	9,316

Three of the principal counties in wheat and milk production give the following figures:

	Wheat (1000 Acres)				
	1912	1913	1918.	1924.	1925.
Essex .	136	128	156	106	96
Norfolk .	136	120	135	99	103
Lincoln .	188	148	224	172	184

	Cows and Heifers in Milk and in Calf (1000)				
	1912.	1913	1918.*	1924	1925.
Chester .	115	111	114	118	127
Lancaster .	138	134	135	142	142
Somerset .	122	120	122	139	138

* Excluding heifers in calf.

The cultivation of sugar-beet may be said to have begun in 1920, and is therefore unnoticed in this atlas, though the acreage has reached nearly 55,000 with a possibility of doubling in 1926.

Nevertheless, with all these limitations, the atlas has great value. It is a permanent record of agriculture as it was in 1918 at the close of the War, and although in an absolute quantitative sense the maps may already be out-of-date, the relative distribution of farm lands, of crops and of live-stock—which is the real value of the atlas—probably still holds true.

Experimental Optics.

Experimental Optics: a Manual for the Laboratory. By Dr. G. F. C. Searle. (Cambridge Physical Series.) Pp. xvi + 357. (Cambridge: At the University Press, 1925.) 16*s.* net.

IT is not often that an original investigator lays aside research work in which he has already established a reputation, and bends the whole of his energy and ability to the art of training others in the spirit and practice of his science. It is, perhaps, particularly rare in that vitally important branch of teaching which has for its province the practical laboratory. There is a certain stimulus in lecturing which makes it a not altogether unwelcome interlude in the day's work; but the demonstrator, who must wrestle year in and year out with errors which remain always the same while students come and go, has no such aid to cheer him in his task. When, however, as sometimes happens, a teacher arises with the faith and insight to find in this too often routine work a suitable outlet for his energy and ingenuity, the results for science are apt to be noteworthy. For, after all, it is in the practical laboratory that the experimental scientist is made or marred. There are many old Cambridge men, teaching or practising physics in various parts of the world, who have passed through Dr. G. F. C. Searle's hands, either as students of the art of experimenting, or as raw beginners in the still more difficult art of teaching practical physics to others, who feel towards him a debt of gratitude the sense of which deepens as the years roll on.

For these no review is necessary. The mere announcement that Searle's "Experimental Optics" is out at last will be sufficient to send them post-haste to the bookseller. They have been waiting for it for a time exactly equal to that which has elapsed since they left 'the class.' They will wish to renew old memories of the time when, having worked conscientiously through six methods of measuring the focal length of a thick lens, they were confronted with the demand that the same processes should be repeated on the telescopic system, or the 'model eye'; to fill up gaps left by the carelessness of youth in now highly prized practical note books; and to see what new experiments have been added to the course since their time. For "Experimental Optics" is not a book written in a hurry to meet some sudden demand. It is the work, we will not say of a lifetime (for we cannot possibly spare Dr. Searle until he has completed this series of laboratory manuals with an "Experimental Heat," and a much-needed "Experimental Electricity and Magnetism"), but certainly the work of many years, and the experiments it describes have been tried out on many generations of students. They are not ingenious suggestions which the author thinks might possibly work. They have been tested and tried, under by no means easy conditions, and have gradually ripened to their present perfection. It is this which gives to these manuals by

Dr. Searle, of which "Experimental Optics" is the latest, their unique value.

It must be confessed that this fact adds somewhat to the difficulties of the present reviewer. It is hard to be correctly calm and critically cool towards a book with some parts of which, in their manuscript form, one has that intense familiarity which comes from actual use in teaching in times past. Its qualities, good or bad, are known with an intimacy which is unbecoming to a reviewer. It says something for the quality of the book that, on re-reading these familiar portions after some long interval, its merits seem even greater than we had remembered, and its defects so few as scarcely to call for comment.

Dr. Searle's method of treating his subject is now well known from his previous books, and "Experimental Optics" does not differ in plan from its predecessors. It is written around the experiments, some seventy in number, which make up the course in practical optics in Dr. Searle's class at the Cavendish Laboratory. Many of these experiments are highly original, and they are described with such care and precision that the reader should have no difficulty in following them out, even in their minuter details. The apparatus is usually of the simplest, such as, for the most part, can easily be constructed in a very modestly equipped workshop (a consideration by no means to be despised in these days when prices are high and funds are meagre), and adequate instructions are given for its construction. The accuracy of measurement obtainable is, however, high, as is shown by the practical examples appended to each experiment, which are usually a record of the work of some student in the class. Dr. Searle's ingenuity and experimental skill is nowhere shown more clearly than in the way in which, by ingenious devices and skilful arrangement, he makes it possible even for the ordinary student to obtain results with this simple apparatus which would not be discreditable in a laboratory equipped with the most elaborate and expensive optical devices. No experiment is left until the utmost accuracy of which it is capable has been extracted from it. Experimental optics is not one of the most popular branches of physics at the moment, but there is no part of the subject which is better calculated to instil that meticulous care and precision in measurement which is now, as always, the basis of physics. A student who works conscientiously through the course described in this book will have learned something greater than practical optics: he will have learned how physical experiments ought to be carried out.

The book, however, is more than a practical manual. The theory involved in each experiment is very adequately dealt with either in an introductory paragraph or in a separate chapter. We have thus an excellent treatise on geometrical optics, written, moreover, in a style which brings it within the range of students whose mathematical equipment is not of the strongest. These theoretical sections are, in fact, exceptionally well done. Personally we feel some regret that Dr. Searle should have followed the "lens manufacturers, opticians, and oculists" in assigning a positive focal length to a thin converging lens, instead of following the practice most commonly adopted in mathematical and physical text-books of assigning a negative value to this quantity. Nearly all students will have learned the latter convention before commencing to read Dr. Searle's manual, and though the introduction of a new convention may provide useful food for thought to a good student, weaker students are almost sure to find it disconcerting, and a little confusing.

In scope the book covers adequately, or even more than adequately, all that a student of physics (as distinct from the technician) will require in geometrical optics. In comparison, the section on physical optics, which occupies less than one-quarter of the whole, seems rather scanty. To devise simple apparatus which will permit of even approximately accurate measurements in interference and diffraction is by no means easy, and we are grateful to Dr. Searle for showing us how, in one or two cases, it can be done. We hope he will find it possible to give us more on this branch of the subject, as these two concluding chapters are as interesting and illuminating as anything in the book.

We have here, then, a text-book on optics, accurate, practical, and original, which every teacher will wish to have, and which, we predict, will find a place in every physics laboratory. Unfortunately, it seems impossible nowadays to publish scientific books at a price which the average student can afford to pay, but we are sure that no student who can contrive to add this volume to his library will have cause to regret his purchase.

J. A. CROWTHER.

Quantitative Biology.

Physical Chemistry in Biology and Medicine. By Prof. J. F. McClendon and Prof. Grace Medes. Pp. 425. (Philadelphia and London: W. B. Saunders Co., 1925.) 21*s*. net.

IN the heyday of evolutionary biology, Francis Galton remarked "that until the data of any branch of human enquiry have been submitted to measurement, it cannot be said to have acquired the dignity of a science." It is strange to think that after thirty years the truth and the falsity of this remark are apparent to all except that branch of the biological public to which it was most particularly addressed. To suggest to a physiologist or to a biochemist that an adequate treatment of his subject is possible without a knowledge of physical chemistry, is as ludicrous as to suggest to a student of heredity that a solution of all his difficulties is to be found in the pages of *Biometrika*. Until recently, however, those sciences most closely associated with Galton and with the idea of evolution have shown little tendency to evolve new methods, and little tendency to acquire the 'dignity' which Galton hoped would grace their later years.

The advance of zoology, for example, has been due to the theory of evolution and to the description of animals at all stages of their life-history, and when we view this imposing contribution to human knowledge, we may perhaps regard the acquisition of further complexity with doubtful pleasure. Yet whether we like it or not, Galton's remark was made to all biologists, and it is for them to refute or affirm. So long as we are content to describe the structure of an organism and draw therefrom a mental conception of its evolution, the realm of zoology will be a peaceful haven for all who enter. But if we wish to regard an animal as a real and dynamic system, and if we wish to apply some logical test to our conclusions as to how it lives and how it evolved, then we must use those methods which are available for the study of *changing* systems, whether these be alive or dead.

The study of life is the study of change, and we can either speculate or we can proceed by logical methods placed in our hands by other sciences. One ventures to think that the pathetic striving of the young zoologist for an accurate measurement of his data is a natural reaction from the speculative hypotheses of the past. His problems are not new, but it is by new methods that he seeks to answer old questions. Like all other fledglings, he has difficulties and disappointments. He grasps the delicate instruments of physical chemistry and finds they may break in his hands. He uses a mathematical notation, and only slowly does he learn its value and its limitations. By far his greatest problem is to choose his weapons with discretion and to learn their use. If Prof. McClendon is to be believed, these weapons vary from a knowledge of the electron to a knowledge of higher mathematics. This is indeed a terrifying thought, and this book may well repulse even the most intrepid reader. With breathless speed the authors lead us across wide fields of learning. There is no time to acquire knowledge or to see the great and real difficulties; there is only time to note the valuable lists of references which close each chapter.

We do not think that this book will help those who—according to the preface—" fail to receive early training which they later feel the need of." Nor do we think that it will greatly help the specialised research worker; the material is too scanty and the treatment is too vague. The real value of this and similar books is that they throw out, once more, the challenge to biology to support its speculations by experiments and to acquire more quantitative 'dignity.'

J. G.

Our Bookshelf.

Handbuch der Zoologie: eine Naturgeschichte der Stämme des Tierreiches. Begründet von Prof. Dr. Willy Kükenthal. Herausgegeben von Dr. Thilo Krumbach. Erster Band: Protozoa, Porifera, Cœlenterata, Mesozoa. Sechste Lieferung. Pp. 737-896. Siebente (Schluss-) Lieferung. Pp. 897-1060+xiv. 12·40 gold marks. (Berlin und Leipzig: Walter de Gruyter und Co., 1925.) 9 gold marks.

THE sixth part of this work opens with an account of the pennatulids which, as would be expected from the pen of the late Prof. Kükenthal, is a thoroughly sound piece of work. One of the few points which permits of criticism is the statement that observations on regeneration are wanting; the work of Torrey and of E. B. Wilson on regeneration in young Renillas was evidently overlooked. The chapter on Octocorallia (anemones, corals, etc.) is by Prof. F. Pax and gives a good account of the structure, biology, and classification. The description of the nervous mechanism is, however, disappointing; it is too general, does not get down sufficiently to facts of detail, and there are no illustrations of the nerve elements.

The seventh part is devoted to accounts of the Ctenophora and the Mesozoa. The editor, Prof. T. Krumbach, has undertaken the preparation of the chapter of 90 pages on the Ctenophora and has produced an admirable account of the structure, biology, geographical distribution, and classification of this class. The diagrams illustrating the structure, the variations in form of different genera, the origin of the creeping habit (*e.g.* in Ctenoplana), and the more detailed figures, many drawn from recent memoirs, afford excellent support to the text, but a better figure illustrating the details of cleavage and early development should have been given. The numerous views which have been put forward by different authors on the affinities of the Ctenophora are exhaustively set forth, even the relationships with sponges; a critical discussion and summary of the matter would have been helpful.

Prof. M. Hartmann describes the Mesozoa (17 pp.) and adds a short account of the imperfectly known genera Neresheimia and Salinella. In his account of the Mesozoa he has omitted to refer to the important contributions of Caullery and Lavallée (1912) and of Lameere (1916, 1917, 1919) which add new facts, and offer new interpretations, that should have received notice in a work of this kind.

The seventh part, completing the first volume of the work, contains a full index thereto and a short notice in remembrance of the late Prof. W. Kükenthal. The volume has, in our opinion, improved in quality, in both text and illustrations, in its later parts, and if the rest of the work can be maintained at the high standard attained in most of the recent chapters, it will certainly be an admirable text-book of descriptive zoology for teachers and advanced students.

Hephæstus: or, The Soul of the Machine. By E. E. Fournier d'Albe. (To-day and To-morrow Series.) Pp. 90. (London: Kegan Paul and Co, Ltd.; New York: E. P. Dutton and Co., 1925.) 2*s.* 6*d.* net.

THE publishers make claim for the "To-day and To-morrow Series" that it has revived the pamphlet as a form of literature. Now a pamphlet, one supposes, should be brief, provocative, and readable. If the author is a little angry, all the better; Milton was angry when he wrote the "Areopagitica" and his treatises on divorce. If the author has several very obvious blind spots, all the better; some one else will immediately write another pamphlet to point them out to him; and so the joyous game of pamphleteering will grow like a snowball.

Dr. Fournier d'Albe is brief, provocative, and readable, but not angry; he is lyrical. His pamphlet is a pæan in praise of the machine, daughter of Hephæstus and Fire, liberator of mankind. "The victories of Hephæstus are victories of mind over matter. The *mechanical age*, which to some appears as the very negation of the soul, is, on the contrary, the age of supreme psychical achievement" (p. 50). "Fire has made all things new" (p. 57). "The whole earth must be Vulcanized" (p. 80). So the European. We may now confidently await the pamphleteer, with sympathies more Asiatic than European, with mind given pause by the speculations of, say, Spengler, who will point out to Dr. Fournier d'Albe that nine-tenths of mankind are still, always have been, and probably always will be, supremely indifferent to, and slightly contemptuous of, any but the most rudimentary form of machine. Modern European civilisation is built on machinery; other civilisations have had other foundations.

J. Y. T. G.

An Introduction to Organic Chemistry. By Prof. Alexander Lowy and Dr. Benjamin Harrow. Pp. ix+389. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 15*s.* net.

BOTH the teacher and student of organic chemistry must at times seem overwhelmed by the enormous and ever-growing mass of material that now constitutes this branch of the science; but, fortunately for both, the subject is well systematised and lends itself well to a broad, general treatment. The work under review can be recommended from this point of view: the outline presented is broad and clear, structural formulæ are numerous and well set out, especial prominence is given to applications in the industrial arts, biochemistry, and pharmacy, and the parts dealing with nomenclature and the meanings of technical terms are very useful.

Although the method of presentation is, in general, not sufficiently didactic for use in secondary schools, and is inclined to be too dogmatic, fact and hypothesis being inadequately differentiated, the book will serve as an excellent introduction for students when used as an auxiliary to a good course of lectures and experimental work. The exclusion from the main body of the text of melting- and boiling-points, and similar physical details, the up-to-date character of the subject matter, and the insertion of some excellent folding charts relating mainly to industrial applications, all help to make the work thoroughly readable and to awaken the interest of the student. The literature references given throughout the book, with the view of inciting collateral reading, add considerably to its value.

Dwellers of the Sea and Shore. By William Crowder. (Hutchinson's Nature Library.) Pp. xv+300+44 plates. (London: Hutchinson and Co., n.d.) 7*s.* 6*d.*

"DWELLERS OF THE SEA AND SHORE" is a true natural history book, and is written by a real naturalist who obviously delights in observing the living animals and plants in their haunts. Although it is published in England as one of "Hutchinson's Nature Library," the reader will not find in it an account of the inhabitants of British shores and seas. The region described is on the American coast not many miles from New York Harbour, and although we have many seashore animals and plants in common, there are of course many differences. This is perhaps really an advantage, as we are given an excellent picture of a foreign shore. The illustrations are good, especially the photographs of living animals taken in the water, and the extremely interesting pictures of the king crab. The chapters on the habits of the individual animals remind one of Fabre, those on the king crab, fiddler and hermit crabs, and the moon snail having a peculiar charm. We gather from the author the sad fact that Limulus, the "living fossil" as he terms it, is in danger of extinction in spite of its great abundance. There is little to criticise in the book, which is a genuine contribution to the biology of sea animals, but why should it be said that brachiopods differ from bivalve molluscs in having both valves similar?

A Summary of Physical Chemistry. By Prof. K. Arndt. Translated from the fourth German edition by W. H. Patterson. Pp. v + 92. (London: Methuen and Co., Ltd., 1925.) 3*s.* 6*d.* net.

THE "Summary of Physical Chemistry" which Mr. Patterson has translated covers 86 pages, apart from the two indexes. It is just the sort of abstract that an able student would prepare in order to recall the essential points of the lectures to which he had listened, and of the text-books which he had read. A ready-made summary of this kind provides a means of 'spoon-feeding' which is likely to be acceptable to many hard-pressed students, but in the opinion of the reviewer they would be well advised to make use of it only after compiling a summary of their own, and then mainly in order to check the completeness of the 'home-made' product. If used in order to provide a supply of 'catch-words,' as a substitute for detailed knowledge, its introduction would be definitely harmful.

An Introduction to the Physics and Chemistry of Colloids. By Emil Hatschek. (Text-books of Chemical Research and Engineering.) Fifth edition. Pp. xiii+183. (London: J. and A. Churchill, 1925.) 7*s.* 6*d.* net.

THE first edition of Hatschek's "Introduction to the Physics and Chemistry of Colloids" appeared in 1913. Since the fourth edition was entirely rewritten, the fifth edition includes only a few additional sections describing recent important advances; apart from these, the text is substantially that of the previous edition.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

International Phenology.

OUR appeal in NATURE of October 25, 1924, and April 25, 1925, for international phenological co-operation has met with unexpected response. We now know that, on the continent of Europe alone, apart from individual workers, networks of observing stations have been established in the following countries:—Holland, under Dr. H. Bos; Belgium, under the late Prof. Vanderlinden; Norway, under Asche Moe; Germany and Austria, under Dr. E. Ihne; Czecho-Slovakia, under Prof. J. Kopecky; Hungary, under Dr. J. Schenk, Tyrol, under Dr. W. Pfaff; North Italy, under Dr. M. A. Minio; Russia in Europe, under Prof. P. Schmidt. Of these, we had previously only been in touch with Holland, Belgium, and Germany.

The total number of stations exceeds two thousand, besides more than three hundred and fifty in the British Isles. Dr A. D. Hopkins carries on similar and more organised work in the United States, and it is developing in western Canada. Numerous isolated observers in Europe and in the more distant British Dominions, Java, etc, are in touch with us. Agricultural colleges are participating more and more as they realise the practical value of phenology.

In order to develop closer co-operation and greater uniformity in method, some suggest holding an international congress and founding a periodical. We are further indebted to Prof. Paul Pelsener, of Brussels, who, at the International Conference of Biological Sciences held there last July, presented our appeal and obtained a resolution recommending their branches in their respective territories to organise phenological work analogous to that of the Royal Meteorological Society.

These results are gratifying, even if conditions are as yet scarcely ripe for a special congress or periodical. But with the help of NATURE we should like to present a definite scheme for observations, based on the valuable criticisms of the suggested list of 43 plants given in last communication. This we have condensed to about 30, and associated with them a few observations of birds and insects, all as tabulated below.

SUGGESTED PHENOLOGICAL SCHEDULE FOR INTERNATIONAL OBSERVATIONS.

	Plants.		Day of Year.
1	*Galanthus nivalis**	Snowdrop	19
2.	*Eranthis hyemalis**	Winter Aconite	20
3.	*Crocus aureus**	Yellow Crocus	33
4.	*Ulmus campestris*	Common Elm	44
5.	*Corylus avellana* ♀ (Female)*	Hazel	44
6.	*Ranunculus ficaria**	Lesser Celandine	47
7.	*Tussilago farfara**	Coltsfoot	65
8.	*Prunus amygdalus*	Almond	85
9.	*Anemone nemorosa**	Wood Windflower	92
10.	*Prunus spinosa**	Blackthorn	102
11.	*Quercus pedunculata*	Stem-seeded Oak	115
12.	*Ribes rubrum*	Red Currant	115
13.	*Alliaria officinalis* or *Sisymbrium alliaria**	Garlic Hedge Mustard	120
14.	*Pyrus malus*	Wild Crab-apple	130
15.	*Syringa vulgaris**	Common (purple) Lilac	130
16.	*Æsculus hippocastanum*	Horse Chestnut	133
17.	*Prunus padus*	Bird Cherry	135
18.	*Cydonia vulgaris*	Quince	135
19	*Cytisus laburnum*	Laburnum	138
20*a*.	*Crataegus oxyacantha**	Hawthorn	139
20*b*	,, *monogyna*	Southern Hawthorn	145
21.	*Chrysanthemum leucanthemum**	Ox-eye Daisy	154
22	*Sambucus nigra*	Elder	160
23.	*Rosa canina**	Dog Rose (pink)	163
24.	*Symphoricarpus racemosus*	Snowberry	165
25.	*Robinia pseudacacia*	White Acacia	190
26.	*Lilium candidum*	Madonna Lily	195
27.	*Castanea vesca*	Sweet Chestnut	200
28	*Scabiosa succisa**	Devil's-bit Scabious	220
29.	*Colchicum autumnale*	Autumn Crocus	245
30.	*Hedera helix**	Ivy	276
31.	*Helleborus niger*†	Christmas Rose	350
	Birds.		
A.	*Turdus musicus* (Song Thrush), in song after Dec 31.		22
B.	*Phylloscopus rufus* (Chiffchaff), heard		95
C.	*Hirundo rustica* (Swallow), arrives		109
D.	*Cuculus canorus* (Cuckoo), heard		114
E.	*Cypselus apus* (Swift), arrives		125
F.	*Muscicapa grisola* (Spotted Flycatcher), arrives		135
G.	Last *Hirundo rustica* (Swallow), leaves		283
	Insects.		
J.	*Apis mellifica* (Honey Bee), visiting flowers		60
K.	*Vespa vulgaris* (Queen Wasp), flying in open		103
L.	*Pieris rapae* (Small White), flying in open		111
M.	*Anthocaris cardamines* (Orange Tip), flying in open		131
N.	*Epinephile janira* (Meadow Brown), flying in open		164

The dates are the average for the thirty years 1891 to 1920 in the British Isles. The plants marked *, and all the birds and insects, are on the British Schedule.

† To be entered on the schedule for the following year

The following, among other points, have governed the selection, after careful comparison of lists from the above nine countries and our own.

(1) That each country may find among them at least ten to twenty plants which are easily accessible. The birds and insects are well distributed over Europe.

(2) That at least a few, as garden growths or wild, shall be found in all temperate regions. Tropical countries it seems most difficult to include.

(3) That the whole phenological year shall be covered. Where observers can undertake the work, we commend further observations, especially with trees, on the date of leafing (trees look green), fruiting, colouring (full tint), and leaf-fall (trees bare). All who can are asked to do this at any rate for *Æsculus hippocastanum*.

(4) For flowering date it is advantageous to select such as bloom quickly, when once buds begin to open.

The stage at which flowering is recorded varies very awkwardly in different countries We suggest the selection of tree, bush, or herb, or better still, a group, situated in the most normal exposure available, neither exceptionally early nor late in maturing, and that on such plant or group the first flower to expose its stamens (or *pistils* for *Corylus avellana*) shall be recorded *if—and only if*—the other buds are about to do the same.

The observer's district should be as concentrated as possible. A five-mile radius should be regarded as the limit, and elevation above sea-level differ as little as possible.

The same plant or group should be observed from year to year, or of herbs a selection from those under similar conditions.

Where they can, British observers are invited to include part or all of the extra plants in a supplementary table.

We wish again to make it clear that there is at present no central body to collect and, above all, tabulate results. This must be done by each country independently, after having circulated to their observers such a list, selected from that subjoined, as best adapts itself to local conditions, including the same as part of, or as supplement to, their present schedule. All the lists sent us already include quite a large number.

In the course, say, of ten years, we may well hope that these records will be collocated and produce, directly and by correlation, interesting data for scientific analysis and also of value for agricultural and other practical applications

Long before then we might have preliminary annual comparisons on special events, and even pan-European isophenal charts, such as Hoffmann and Ihne have given us for much of western Europe.

As an initial step, and by way of a practical experiment, we suggest the preparing by each network of stations four isophenal charts of their area for 1926, namely, one each for *Prunus spinosa* (102), for *Hirundo rustica* (109), *Pieris rapae* (111), and *Cuculus canorus* (114), sending a copy to our Committee, that each of the four may be combined to form one of Europe. The interest would lie in investigating how far the relative dates in one part of the continent held from region to region.

Finally, we would appeal again to the other British Dominions, especially in the sub-continent, asking them in their countries also to collaborate so far as possible with the older countries in this work.

Zoological Nomenclature.

THE Secretary of the International Commission on Zoological Nomenclature has the honour to announce the publication of Opinions 82 and 90, rendered by the International Commission on Zoological Nomenclature, by the Smithsonian Institution in *Smithsonian Miscellaneous Collections*, vol. 73, No. 3, pp. 1-40. The summaries read as follows:

Opinion 82. Suspension of Rules for Musca Linnæus, 1758a, type *M. domestica*. By authority of the power conferred on the Commission by the ninth International Congress of Zoology to suspend the Règles as applied to any given case where in its judgment the strict application of the Règles will clearly result in greater confusion than uniformity, Article 30 is hereby suspended in the case of Musca Linnæus, 1758, and *Musca domestica* Linnæus, 1758, is hereby designated as type of Musca without prejudice to other cases.

Opinion 83. *Acanthiza pyrrhopygia* Vigors and Horsfield, 1827, versus *Acanthiza pyrrhopygia* Gould, 1848. The principle of the Rule of Homonyms is that any properly published identical name of later date is "stillborn and cannot be brought to life." *Acanthiza pyrrhopygia* Vigors and Horsfield, 1827, invalidates *Acanthiza pyrrhopygia* Gould, 1848.

Opinion 84. Trematode, Cestode, and Acanthocephala names placed in the Official List of Generic Names. The following names are hereby placed in the Official List of Generic Names: Trematoda: Dicrocoelium, Fasciola, Gastrodiscus, Heterophyes. Cestoda: Davainea, Dipylidium, Echinococcus, Taenia. Acanthocephala · Gigantorhynchus.

Opinion 85. Ninety-eight generic names in Crustacea placed in the Official List of Generic Names. The following names are hereby placed in the Official List of Generic Names: Crustacea: Acmaeopleura, Asthenognathus, Bathyplax, Camptandrium, Camptoplax, Catoptrus, Ceratoplax, Chasmagnathus, Chasmocarcinus, Clistocoeloma, Cyrtograpsus, Dissodactylus, Durckheimia, Epixanthus, Euchirograpsus, Eucrate, Eucratodes, Eucratopsis, Euryetisus, Euryplax, Eurytium, Fabia, Galene, Geryon, Glyptograpsus, Glyptoplax, Gomeza, Goneplax, Halimede, Helice, Hephthopelta, Hexapus, Holometopus, Holothuriophilus, Homalaspis, Lachnopodus, Leptodius, Liagore, Libystes, Liomera, Lipaesthesius, Litocheira, Lophopanopeus, Lophopilumnus, Lybia, Melybia, Metasesarma, Metopocarcinus, Micropanope, Notonyx, Oediplax, Ommatocarcinus, Opisthopus, Orphnoxanthus, Panoplax, Paragalene, Parapanope, Parapleurophrycoides, Paraxanthus, Percnon, Perigrapsus, Pilumnoides, Pilumnus, Pinnaxodes, Pinnixa, Pinnotherelia, Pinnotheres, Planes, Platychirograpsus, Platypilumnus, Platyxanthus, Polydectus, Prionoplax, Pseudocarcinus, Pseudopinnixa, Pseudorhombila, Psopheticus, Ptychognathus, Pyxidognathus, Rhithropanopeus, Rhizopa, Ruppellioides, Sarmatium, Scalopidia, Scleroplax, Speocarcinus, Sphaerozius, Tetraxanthus, Tetrias, Thaumastoplax, Utica, Varuna, Xanthasia, Xanthodius, Xenophthalmodes, Xenophthalmus, Zosimus, Zozymodes

Opinion 86. Conulinus von Martens, 1895. The generic name Conulinus von Martens, 1895, takes as type *Buliminus* (*Conulinus*) *conulus* Rv, and is not necessarily invalidated by Conulina Bronn.

Opinion 87. The status of proof-sheets in nomenclature. Printer's proof-sheets do not constitute publication, and therefore have no status under the International Rules of Zoological Nomenclature.

Opinion 88. *Otarion diffractum* vs. *Cyphaspis burmeisteri*. The name of a species is not disqualified merely because the author included in his conception bodily parts of more than one species. The name of a genus based on such a species is therefore available *Otarion diffractum* Zenker is valid. Otarion is to be preferred to Cyphaspis, and *C. burmeisteri* Barr. is a synonym of *O. diffractum*.

Opinion 89. Suspension of the rules in the case of Gronow 1763, Commerson 1803, Gesellschaft Schauplatz 1775 to 1781, Catesby 1771, Browne 1789, Valmont de Bomare 1768 to 1775. Under suspension of the rules, in any case where such suspension may be considered necessary according to the interpretation now or hereafter adopted by the Commission, the following works or papers are declared eliminated from consideration as respects their systematic names as of their respective dates: Gronow 1763, Commerson 1803, Gesellschaft Schauplatz 1775 to 1781, Catesby 1771, Browne 1789, Valmont de Bomare 1768 to 1775.

Opinion 90. Report on sixteen generic names of mammals for which suspension of rules was requested. None of the sixteen names receives a unanimous vote for suspension; accordingly, the Commission is not empowered to suspend the rules for these cases. Six names (namely: Cercopithecus, Gazella, Hippotragus, Lagidium, Nycteris, and Manatus) receive two-thirds majority or more for suspension, and are, therefore, to be referred for final decision to a special committee of three to be appointed by the president of the section on nomenclature of the next international congress. Ten names (namely: Echidna, Anthropopithecus, Coelogenys, Chiromys, Dasypus, Dicotyles, Galeopithecus, Hapale, Rhytina, and Simia) fail to receive a two-thirds majority vote for suspension, and therefore the law of priority is to be applied in these cases C. W. STILES (Secretary).

International Commission on Zoological
Nomenclature.

The Isomeric Chromic Chloride Hexahydrates.

THE Werner formulation for the dark-green chromic chloride hexahydrate, namely, $[CrCl_2(H_2O)_4]Cl,2H_2O$, has been criticised recently by Britton (*J. Chem. Soc.*, 1925, 127, 2128), who offers the alternative view that the basic chromium complexes apparently present in green solutions are "micellar" in structure and virtually constitute a colloidal electrolyte in which the cations are composed of chromium hydroxide and varying amounts of acid radical, a portion only being ionisable. This view accounts for the fact that green salts show greater resistance towards alkali than the analogous violet modifications.

In an endeavour to confirm the Werner formulation for the three chromic chloride hexahydrates, we had commenced a series of viscosity determinations on aqueous solutions of these salts. Three such hydrates are known:

Name.	Colour.	Werner Formula.
Hexa-aquo chromic chloride .	Violet	$[Cr(H_2O)_6]Cl_3$
Monochloro-penta-aquo chromic chloride monohydrate .	Blue-green	$[CrCl(H_2O)_5]Cl_2,H_2O$.
Dichloro - tetra - aquo chromic chloride dihydrate . . .	Dark-green	$[CrCl_2(H_2O)_4]Cl,2H_2O$.

The violet hydrate is unstable in the solid state and passes slowly into the dark-green hydrate; the latter, which is stable in the solid state, passes into the violet form in solution. The intermediate hydrate is unstable in the presence of moisture; it changes to the dark-green form, and measurements on its solutions were not attempted.

The comparative flow method of measurement was used, a viscosimeter of the type described by Martin (*Bull. Soc. Chim. Belg.*, 1925, 34, 81) being found to give very consistent readings. Our measurements are summarised in the following table, η/η_{H_2O} representing the ratio of the viscosity of the solution to that of water at the same temperature.

Dark-green Chloride.		Violet Chloride.	
Wt. of Hydrated Salt per 100 gm. of Water.	η/η_{H_2O}	Wt. of Hydrated Salt per 100 gm. of Water.	η/η_{H_2O}.
Temperature 25°.			
50·32	1·8095	62·20	3·3571
35·67	1·5397	33·64	1 9206
21·50	1·3333	20·61	1·4841
16·34	1·2462	17·58	1·3968
12·91	1·1984	16·27	1·3730
6·35	1·1111	11·23	1·2381
3·58	1·0635	8·48	1·1944
		5·75	1·1270
		3·68	1·0793
Temperature 18°.			
52·40	1·8904	40·18	2·1644
36·36	1·5616	26·82	1·6575
24·80	1·3493	16·81	1·4315
22·38 [1]	1·2808	13·57	1·3356
17·07	1·2329	9·44	1·2123
12·79 [2]	1·1507	8·02	1·1849
10·04	1·1166	5·48	1·1164
6·86	1·0890	3·46	1·0753
4·05	1·0548	1·63	1·0342

[1] This was a freshly prepared solution.

[2] This solution was freshly prepared; the subsequent solutions were obtained from it by progressive dilution.

The figures in the fourth decimal place under η/η_{H_2O} are not wholly reliable. The figures for dilutions greater than 5 gm. per 100 gm of water should be accepted with reserve.

The dark-green solution changes to violet with time; it follows that, except for those cases in which solutions have been freshly prepared, the figures for the dark-green chloride are too high. In any case, for equivalent salt concentrations, the viscosities of the violet chloride solutions are much higher than those of the corresponding green solutions.

This is in qualitative agreement with the formulæ assigned to the two salts by Werner. Presumably, the co-ordinated nucleus affords the greater contribution to the viscosity of the solution, and one would expect solutions containing the larger nucleus to be more viscous than those containing the smaller one. In other words, one would expect violet solutions to show a higher viscosity than the analogous green ones; experiment confirms this. On Britton's view the exact opposite should hold, since he considers the green solutions to be colloidal in nature. Endeavours are being made to apply the above results quantitatively.

A paper has recently appeared by Birk and Biltz (*Z. anorg. Chem.*, 1925, 150, 20) in which the molecular volumes in petroleum of the chromic chloride hexahydrates are recorded. The molecular volumes are found to increase with decreasing stability, *i.e.*, in the order dark-green, violet, and blue-green. The molecular volumes of the water in the three salts are given as 14·7, 15·2, and 15·7, respectively. Presumably, therefore, if these figures are correct, the unstable blue-green salt should give solutions even more viscous than solutions of the violet salt.

An X-ray examination of the salts has been commenced with the object, if possible, of elucidating the relative positions of the water in the nucleus and the water of crystallisation, and so forming an ultimate confirmation or negation of the applicability of Werner's ideas to these compounds.

February 4.

On Nocturnal Colour Change in the Pea-crab (*Pinnotheres veterum*).

WHILE investigating the moulting stages of pea-crabs, a nocturnal colour change—analogous to that described by Gamble and Keeble in Hippolyte (*Quart. Journ. Micros. Sci*, 1900; *Phil. Trans. Roy Soc.*, B, 1903, 1905)—was observed by me in what is apparently *Pinnotheres veterum*. Last June I received from the Marine Biological Association, Plymouth, an ascidian (*A mentula*) which had been dredged off the Mewstone, and from the branchial chamber of which a pea-crab had been found attempting to escape By the time it reached me two crabs had escaped, a male and a berried female. These are most probably *P. veterum*

P. veterum is the pea-crab which inhabits the Pinna of the Mediterranean and is also found in the large Pinna of the Salcombe Estuary in Devonshire. It has been recorded as well from parts of the Irish coast in Pinna and Modiola *P. veterum*, however, is much less common than *P. pisum*, the pea-crab which is found living within the mussel (*Mytilus edulis*), as well as in other bivalve molluscs.

It so happened that the paper lining of the lid of the jar in which the ascidian and crabs travelled from Plymouth had become sodden and had fallen into the water in numerous small pieces. After the contents of the jar had been turned into a bowl and allowed to rest for a while, it was noticed that the crabs had hidden themselves beneath the paper. When uncovered they proceeded to hide themselves again, sidling under the fragments, and throwing them on to their backs with their legs. The female being of considerable size (11 mm. in width) had more difficulty in hiding itself and made more use of its legs in placing pieces of paper on its back. Occasionally it was seen holding there fragments of paper, and once a tiny empty bivalve shell. The last two or three pairs of legs were used in these operations, and not the chelipeds, as perhaps one might have expected. The dactyli of the legs of this crab are long and curved. When in hiding the antennules were withdrawn.

At night the crabs came out of hiding and were very active. The female appeared at dusk; the male some while, an hour or an hour and a half, later. The nights being very short in June, the crabs were only active for a few hours out of the twenty-four. The more tardy male never showed itself until 10.30 P.M., and was hidden again soon after daybreak, about 5 A.M. Summer Time.

If at night the crabs were brought into the light they almost immediately made efforts to hide themselves. Their activity in the dark was accompanied in the male by loss of colour. In daylight or in a lighted room the dorsal surface of the male crab was a golden brown, shaded with dark brown, and more richly coloured anteriorly than posteriorly. This coloration was due to the presence of orange and dark brown chromatophores, which in this condition were so expanded and their pigment so diffuse as to be almost invisible with a low power of the microscope. In the dark the male became pallid and transparent, the food in the stomach and intestine showing black and the testes white. This loss of colour is due to the retraction of the pigment in the chromatophores induced by the onset of darkness. When the chromatophores were quite contracted some faint yellow diffuse pigment was visible towards the centre of the carapace. The orange pigment appeared to have a quicker rate of flow than the dark brown, and contracted to a smaller area; it is probable that it is lodged in a smaller cell than the dark brown. It appeared as irregular patches of reddish brown or deep orange pigment near the more dendritic or stellate dark brown chromatophores. The ventral surface of the male crab was pale, with very few chromatophores.

The female *P. veterum* had a dirty appearance, but seemed to have no definite colour, and after being in the dark there was no appreciable change in its appearance. I was unable to make out chromatophores in this female, though I have seen them in other adult females which had a definite brown colour.

It is interesting that the male *P. veterum* which suffered nocturnal loss of colour only came out of hiding after it had been really dark some considerable time, while the female appeared at dusk

During the day the experiment was tried of covering the crabs' bowl with something dark. This was done several times, and on a few—but not all—occasions the crabs came out of hiding in about forty to sixty minutes, the male gradually losing colour during this time. When the bowl was uncovered and the crabs exposed to light, the male took about the same time to recover its colour.

The crabs were kept under observation for about forty days. The conditions were unfavourable, for they were kept without change of water and without the addition of food. After about a month the male *P. veterum* failed to react to the stimulus of light, the chromatophores remained expanded at night and the crabs did not hide themselves during the day. It is hoped to continue the observations in the near future.

D. ATKINS.

The Laboratory, Citadel Hill, Plymouth.

Magnetic Storm of February 23-25, 1926.

FEBRUARY 1926 was characterised by rather considerable magnetic activity, there being during the month only four really quiet days, namely, February 6-9. The outstanding feature of the month was the storm of February 23-25, which, as regards duration, was of greater magnitude than that of January 26-27, some aspects of which were discussed in NATURE by Father J. P. Rowland, S.J. It will be noticed that the storms were separated by an interval of twenty-eight days.

According to the Eskdalemuir records, the first movements definitely associated with the February storm began shortly after 23 d 14 h. From about that time until 24 d. 1 h. the geographical north (N) and west (W) components of force were mainly in excess of the normal quiet-day values (as derived from the records on the four days mentioned above), and during this interval fluctuations of considerable magnitude occurred in N and, to a less extent, in W. For several hours after 24 d. 1 h., N and W were definitely in defect of their normal values; the ranges of movement were less than in the earlier part of the storm, but there was very considerable short-period oscillatory movement after about 5 h. From 24 d. 9 h. and 24 d. 13 h., W and N respectively were, on the whole, above normal until about 19 h. Thereafter N remained mainly below normal for several hours, while W was less than normal until shortly after 25 d. 2 h. Irregular disturbance ceased soon after noon on February 25. The largest and most rapid changes in N and W, and the absolute extreme values attained during the storm, occurred during the *post-meridiem* hours of February 24. The times of occurrence of the extreme values were. N: maximum, probably between 16 h. 10 m. and 16 h. 50 m.; minimum, 21 h. 13 m. W: maximum, 16 h. 13 m.; minimum, 21 h. 18 m. The corresponding ranges were: N, >580γ, W, 550γ ($1\gamma = 10^{-5}$ c.g.s. unit).

Vertical (downward) force, V, began to increase from 23 d. 14 h. and remained considerably above the normal undisturbed value during the greater part of the ensuing twelve hours. The sequence of changes during the first part of this interval were somewhat similar to those which occurred in the corresponding stages of the storm on January 26; in particular may be mentioned the broken increase between 16 h. and 18 h. and the two maxima, near 19 h. 30 m. and 21 h. respectively (the earlier being the greater), on each occasion. For about ten hours after 24 d. 2 h. V was below the normal undisturbed value, the lowest value during the first part of the storm being reached at 24 d. 6 h. 44 m. After noon on that day a fairly rapid increase set in. Between 14 h. and 16 h. oscillations of considerable magnitude were superimposed on the general increase. The absolute maximum of the storm occurred between 16 h. 14 m. and 17 h. 42 m., the spot of light passing beyond the limit of the photographic paper during this interval. V decreased fairly rapidly but irregularly between 19 h. and 22 h., and thereafter more gradually to 25 d. 2 h. 40 m., when the minimum value was reached. V was below the normal undisturbed value throughout the interval 24 d. 22 h. to 25 d. 8 h. The recovery from the minimum value was accompanied by pulsations of a few minutes period, but these small changes were less strongly developed than those during the corresponding stages of the January storm. The absolute range in V in the February storm exceeded 560γ.

The ranges in N, W, and V during the interval 23 d. 14 h. to 24 d. 12 h., *i.e.* during the earlier part of the storm, were 386γ, 225γ and 314γ, and therefore distinctly less than the ranges in the later part. It will be seen that the storm of February 23-25 reached its greatest development during the second part of its course and so differed from the January storm, in which the extreme values, together with the largest and most rapid changes, occurred during the first thirteen or fourteen hours. The rapidity of the irregular changes during the phase of greatest disturbance was less in the February than in the January storm. In regard to the absolute ranges in the three components in the two storms, exact data are lacking in the case of N and V, for the record was 'off the sheet' in the neighbourhood of either one or both of the extreme values in each case; but it seems probable that the ranges in N and V in the February storm were not greatly, if at all, inferior to those in the January storm. During the latter the range in W exceeded that in the February storm by about 180γ. A rather interesting feature is that in all three components the minima were higher, *i.e.* less in defect of the normal undisturbed value, in the February than in the January storm.

Aurora was not visible from this locality, which was enveloped in low cloud throughout the course of the storm; but reports of aurora observed elsewhere would be of interest. H. W. L. ABSALOM.

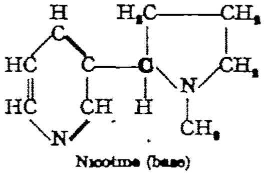
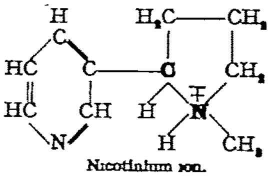
Asymmetric Nitrogen Atoms in Natural Products.

IT has been generally admitted that, although optical activity can be developed in compounds containing asymmetric atoms of carbon, nitrogen, phosphorus, arsenic, sulphur, selenium, tin, etc., as well as in "centro-asymmetric" compounds in which no asymmetric atom can be detected, all naturally-occurring compounds owe their optical activity to the presence of one or more asymmetric carbon atoms. It is, therefore, somewhat of a surprise to discover that the salts of nicotine contain an asymmetric nitrogen atom, in addition to the asymmetric carbon atom to which the free base owes its optical activity, since it was believed that the former type of asymmetric atom was only to be found in laboratory products. It is nevertheless clear, from the formulæ set out below, that the addition of a proton to the nitrogen atom of the pyrrolidine ring of the base does in fact convert this atom into a quaternary ammonium ion, which is linked to four different radicals, and must therefore be regarded as asymmetric, whatever opinion may be held as to the asymmetry of the tri-substituted ammonia from which it is derived.



Nicotine (base)



Nicotinium ion.

These deductions from the structural formula of nicotine receive a partial verification in the fact that the rotatory power of the salts of nicotine, *e.g.*, $[\alpha]_D = +18{\cdot}85°$ for the acetate, is of opposite sign to, and much smaller than, that of the free base, for which $[\alpha]_D = -169°$. This anomaly is not observed in compounds such as camphorsulphonic acid, where the formation of a salt is not accompanied by any fundamental change either in the character of the asymmetric system or in the optical rotatory power of the acid; but it is well known in alkaloids such as narcotine. Several cases are also known in which the rotatory power of a benzoyl-derivative differs widely from that of the free base.

Further verification of the view set out above is found in the fact that (according to a preliminary series of experiments made by Prof. B. K. Singh) the rotatory dispersion of nicotine acetate is "complex," depending on the superposition of at least two "simple" partial rotations, whereas the base itself exhibits only a "simple" rotatory dispersion (Lowry and Singh, *Comptes rendus*, 1925, 181, 909), thus suggesting that a new partial rotation has been developed on converting the base into its acetate.

A series of additional experimental tests has been arranged, and it is proposed to extend the inquiry to other cases in which an asymmetric nitrogen-atom may be developed in derivatives of an optically-active base. T. M. LOWRY.

Abnormalities produced by Amniotic Pressure, and their Relation to Heredity.

IN his review of Haecker's work on pluripotency published in NATURE of November 28, 1925 (vol. 116, p. 776), Prof. MacBride stated that according to researches of Jansen in Holland, Tornier in Germany, and Sir Robert Jones in Great Britain, polydactyly and brachydactyly are both due to pressure of the amnion on the growing rudiments of the fingers, when too little amniotic fluid is secreted during embryonic development. I know from my own experiments that polydactyly is hereditary, and from the observations of others that brachydactyly is likewise hereditary. Does Prof. MacBride really believe that these abnormalities are produced by mechanical pressure of the amnion on the embryo and are at once in the following generation developed by heredity? Such a belief is contrary to the general trend of all the evidence concerning the question of the heredity of somatic modifications. In the case of lizards it is possible, by cutting off the tail and dividing the stump, to obtain lizards with two regenerated tails, but I have never heard it even suggested that the offspring of lizards so treated develop two tails by heredity.

In his letter in NATURE of February 13, p. 232, Prof. MacBride writes: "we can show in the case of Vertebrata that 'mutations' as apparently diverse in nature as mental defect and supernumerary fingers can be explained as due to varying degrees of abnormal amniotic pressure." This is a contradiction in terms: if the abnormalities mentioned were mutations they would not be due to amniotic pressure, and if they were due to amniotic pressure they would not be mutations.

If the abnormalities to which Prof. MacBride refers are not hereditary, the matter is of little importance, but if he means that they are hereditary, like the abnormalities usually described under the names polydactyly and brachydactyly, it would be interesting to know what is the evidence on which his statements are based. He will probably reply that I can read the evidence in the papers of the authors whose names he has given. But he has not given references to their papers; and, further, he is responsible for his own statements implying or suggesting that a hereditary abnormality (for that is the usual meaning of mutation) may be produced in a single individual by mechanical pressure in the embryonic stage of development. It seems to me that other biologists have a right to ask him either to justify or withdraw his statements. J. T. CUNNINGHAM.

On the Polarised Emission of Mercury Lines.

EXPERIMENTS are in progress in which the mercury spectrum is excited by a directed stream of electrons from an oxide coated filament, and the polarisation of the lines examined. The track of the electron beam in a field-free space at a pressure of 1/1000th mm. is well defined, and little visible light is emitted from points not in the path of the electrons. Accelerating voltages of 30-40 volts have mainly been used, and the light from the stream is observed at right angles to its direction. Under these conditions a number of p-d combinations are polarised, the plane of polarisation being with the maximum electric vector parallel to the stream. The plane of polarisation rotates with the tube and so cannot be governed by any stray field.

The following are the lines so far tried, the brackets indicating lack of separation:

Polarised.		Unpolarised.	
λ 5791 Å.U.	$\left\{\begin{matrix}2P-3D\\2P-3d_3\end{matrix}\right\}$	λ 5461 Å.U.	$2p_1-2s$
5770	$2P-3d_2$	4916	$2P-3S$?
$\left\{\begin{matrix}4347\\44\\39\end{matrix}\right.$	$\left.\begin{matrix}2P-4D\\2P-4d_2\\2P-4d_3\end{matrix}\right\}$	4358	$2p_2-2s$
		4108	$2P-4S$
$\left\{\begin{matrix}3906\\04\\02\end{matrix}\right.$	$\left.\begin{matrix}2P-5D\\2P-5d_2\\2P-5d_3\end{matrix}\right\}$?	4078	$2p_2-2S$
		4047	$2p_3-2s$
		3650	$2p_1-3d_1$
3663	$\left\{\begin{matrix}2p_1-3D\\2p_1-3d_2\end{matrix}\right\}$		
3655	$2p_1-3d_3$		

It is seen that the effects on combinations involving the various d and D levels are not completely disentangled, but that the results seem consistent with the view that the polarisation occurs in the case of combinations of the p or P levels with the D, d_2, and d_3 levels.

In the case of the yellow mercury lines 5770 and 5791, the effects can be investigated visually, using a filter. It has been found that the degree of polarisation decreases as the speed of the electrons is increased. At 20 volts the polarisation is about 20 per cent., but falls to less than 3 per cent. for an exciting voltage of 70 volts. Further, the polarisation of the light emitted directly from the path of the electrons can be distinguished from the smaller degree of polarisation of the light emitted from points outside the path of the stream. This seems to lead definitely to the conclusion that the polarisation is caused by the directed character of the electron stream.

The polarisation of the yellow lines is reduced to zero by a magnetic field of about 20 gauss at right angles to the stream and in the direction of observation, but a similar field parallel to the stream has no effect. The same field perpendicular to the stream and to the direction of observation reduces the amount of polarisation to roughly half its value. It remains to be seen whether balancing out the earth's field will bring to light any further effects.

The polarisation of the D lines of sodium excited by a directed stream of electrons has independently been investigated by Kossel and Gerthsen (*Ann. der Phys.*, 77, 273, 1925), but no effect was found; and just as this note was prepared, a paper of Ellett, Foote, and Mohler (*Phys. Rev.*, 27, 35, 1926) came to hand. Using a very low vapour pressure and exciting voltages only a little greater than the corresponding excitation potentials, they studied the cases of the sodium D lines, again with a negative result, and of the mercury line 2537, in which case they found a polarisation of 30 per cent. with the maximum electric vector *perpendicular* to the direction of the stream, that is, in a plane at right angles to that in which polarisation has been found in the case of the p-d combinations. As these authors point out, theoretically we should expect a polarisation with the maximum electric vector parallel to the stream, as is observed in the cases referred to in the present note. The decrease of the magnitude of the polarisation with increasing speed of the exciting electrons and the influence of the application of a magnetic field are also effects which may be interpreted theoretically.

The Leaping Salmon.

WHEN Dr. Starr Jordan says "All salmon will leap over a waterfall where it is possible" (NATURE, January 16, p. 85) he surely refers to salmon in countries like America and Norway, where spring fish do not occur. In Britain salmon enter fresh water, in very many rivers, in every month of the year, and those which do so in the cold-water months—February, March, January, and April, to mention them in the order of coldness—do not leap at falls.

On arrival at the foot of a fall where there is much white water, even when the fall is only a few feet high, all farther ascent is stopped until the wintry thermal conditions have passed. In Scotland, this is usually about the third week in May

Another point to which, perhaps, I might venture to direct attention is the title of the illustration of the leaping salmon. This gives the impression that the particular fish shown is leaping a fall 30 feet high. This must mean that the falls of this Oregon river are really a series of cascades, since no salmon can leap anything like 30 feet. Provided there is a deep pool below the fall, from the bottom of which a fish can make a rapid upward swim, a salmon can leap about 8 to 9 feet vertical height. I have seen a sea-trout of apparently only about 2½ lb. do the same.

Re-Paging of Reprints.

I THINK every one will agree that one of the worst crimes of an author is to give wrong references. Will you kindly allow me to point out that a very frequent source of such errors arises from the re-paging of authors' separate copies? In my editorial work for the *Geological Magazine* I find many instances, and have learnt by experience always to mistrust and verify a reference giving page 1. It is easy to understand that foreign and colonial writers are specially likely to fall into this trap, as often they must rely on authors' reprints and have not a complete series of the periodical at hand.

The practice mentioned is very hard on both authors and editors, besides adding unnecessarily to the cost of reprints.

R. H. RASTALL.

Christ's College, Cambridge.

On One-Eyed Vision.

IN continuation of Sir Arthur Schuster's letter, February 28, p. 228, I feel sure that a person looking with one eye, when time enough is allowed for attention, substitutes for the doubleness of appearance utilised by two eyes a slight unconscious waggle of the head, and thereby secures the needed parallax.

Also I recall that once, glancing over back premises in London with one eye, I caught a glimpse of a cat walking on a near wall which looked surprisingly like a tiger on a far wall.

OLIVER LODGE.

Italy, February 19.

Peregrine Phillips, the Inventor of the Contact Process for Sulphuric Acid.

By Sir ERNEST COOK, D.Sc.

IT is unfortunately the usual fate of the inventor of a novel process of chemical manufacture to find that his monetary reward is little or nothing and that even his name soon ceases to be associated with the process. But probably in few instances is there so little known about the author of an important new method as in the case of Peregrine Phillips, the inventor of the 'Contact Process' for the manufacture of sulphuric acid. Possibly this is partly due to the long period that elapsed between the publication of the patent and the successful working of the process; and yet the broad details as practised to-day were described with fair accuracy in the application for protection originally asked for.

There can be little doubt that this method of manufacturing the acid is growing in importance every day—spacious and well-appointed works, erected at considerable cost, are either already started or soon will be, in Great Britain and other countries. The chamber method, which has served for so long a period, is gradually being superseded and will probably cease to exist as a commercial proposition in a few years' time.

This development has naturally directed attention to the personality of the original patentee. Who was he? Where did he live? What else did he do in the way of scientific discovery? In these respects we are figuratively up against a blank wall. Practically all that is known about him is contained in the specification of his patent; this states that ". . . PEREGRINE PHILLIPS, Junior, of Bristol, Vinegar Maker, send greeting."

The patent was applied for in 1831 and duly granted. It cannot be said that these particulars afford an extensive history of one who has given to the world the means of making an important advance in useful practical knowledge. This is regrettable, and in order to see if other details could be discovered I have made a search of such local records as could be consulted. The result, whilst not telling us much about the scientific career of the author, throws some light upon his business activity. Collecting the facts, the story is as follows.

Since the middle of the seventeenth century there have been several families of the name of Phillips amongst the inhabitants of Bristol, but no representative combining with that surname the Christian name of Peregrine appears until 1803. In that year a Peregrine Phillips opened a tailor's shop in Milk Street in that city. Here he continued to reside and work at his trade until 1831. I think we may consider that the business was fairly successful, because we find that in 1824 he was able to join one John Thorne in starting a business for the manufacture of vinegar at what must have been fairly large works at that time, at 48 Thomas Street. At the present time 48 Thomas Street is a part of the premises of a large hauliers' business, the buildings being of modern date. In 1824 the district was partly residential, with fairly large houses with several courtyards. Messrs. Phillips, Thorne and Co. adapted this house to their requirements and equipped it with suitable apparatus. Apparently this was done very successfully, because I find that vinegar-making was carried on here until 1865—a period of more than forty years. This venture also enabled him to find an opening for his son Peregrine, junior, who became the inventor of the sulphuric acid process. I think it may be taken as certain that Peregrine Phillips, jun., was born in Milk Street, Bristol, and was the son of the tailor, but I have quite failed to find any record amongst the local church registers (the only ones kept in those days), or the newspaper announcements in existence at the time, of the actual date of his birth. The similarity of name, and the association in business, leave little doubt of the relationship of father and son.

Whether the son took a hand in his father's business is doubtful, but judging by the wording and scope of the patent, I think we may conclude that he was well educated and possessed a considerable amount of sound scientific knowledge.

Nothing further is recorded about the firm until July 1831, when there appeared in the issue of *Felix Farley's Journal* for July 11, 1831, the following notice:

> Notice is hereby given that the Partnership between the undersigned PEREGRINE PHILLIPS, the elder, JOHN THORNE, and PEREGRINE PHILLIPS, the younger, of the City of Bristol, vinegar makers, was dissolved by mutual consent on the 13th day of June last, so far as respects the said PEREGRINE PHILLIPS, the younger.
>
> PEREGRINE PHILLIPS, Senior.
> JOHN THORNE.
> PEREGRINE PHILLIPS, Junior.
>
> *Witness*—Andrew Livett, Solicitor.
>
> The above business will in future be carried on under the firm of Phillips and Thorne by whom all the affairs of the above partnership will be settled.

This notice tells its own story. From it we can conclude that the business was not sufficiently prosperous to satisfy the ambitions of the three partners. But whether the dissolution of partnership was brought about by the dissatisfaction of the younger man with his prospects, or by the dissatisfaction of the older men with the attention to the business given by Peregrine, junior, we can only conjecture. In all probability both these considerations came into the problem.

The important patent which has given Peregrine Phillips, jun., a very high place amongst the comparatively short list of those inventors who have introduced a really new process of manufacture of an article of primary importance in all kinds of industries, was applied for in the early days of the year 1831. The licence was granted on March 21, the "particular description of the nature" of the invention made known on July 15, and the patent inrolled on September 14.

The patent is numbered 6096, A.D. 1831, and consists of two parts, in the first of which the inventor describes the plan he proposes for causing the combination of "sulphurous acid gas with the oxygen of the atmosphere" by making these gases pass through hot tubes containing finely divided platinum and other substances. In the second part he describes how he will obtain a more perfect condensation of the sulphuric acid when it is made. The whole document, obviously drawn up with the aid of those learned in the law, makes very interesting reading, and I venture to copy it in its entirety:

A.D. 1831 . . . . . *Patent No.* 6096.

Manufacture of Sulphuric Acid.

Phillips' Specification:

To all to whom these Presents shall come, I, Peregrine Phillips, Junior, of Bristol, Vinegar Maker, send greeting.

Whereas His present most Excellent Majesty King William the Fourth, by His Letters Patent under the Great Seal of Great Britain, bearing date at Westminster, the Twenty-first day of March, in the first year of His reign, did, for Himself, His heirs and successors, give and grant unto me, the said Peregrine Phillips, His special licence, sole privilege and authority, that I, the said Peregrine Phillips, my exors, admors, or assigns, or such others as I, the said Peregrine Phillips, my exors, admors, or assigns, should at any time agree with, and no others, from time to time and at all times during the term of years therein mentioned, should and lawfully might make, use, exercise, and vend, within England, Wales and the Town of Berwick-upon-Tweed, my Invention of "Certain Improvements in Manufacturing Sulphuric Acid commonly called Oil of Vitriol"; in which said Letters Patent is contained a proviso that I, the said Peregrine Phillips, shall cause a particular description of the nature of my said Invention, and in what manner the same is to be performed, to be inrolled in His said Majesty's High Court of Chancery within six calendar months next and immediately after the date of the said in part recited Letters Patent, as in and by the same, reference being hereunto had, will more fully and at large appear.

Now know ye, that in compliance with the said proviso, I, the said Peregrine Phillips, junior, do hereby declare that the nature of my said improvements are herein set forth and explained; but for the better understanding of the subject I shall first describe the present mode of manufacturing sulphuric acid, next, the improvement I propose to effect, and then the means by which those improvements are effected.

Sulphuric acid or oil of vitriol is generally manufactured at present by the combustion of sulphur or brimstone and saltpetre, either mixed together and placed in large leaded chambers or separately in ovens connected with these chambers, into which chambers more or less of atmospheric air is admitted. The sulphur at first is converted by the combustion into sulphurous acid gas, and then by the agency of nitrous gas united with oxygen from the atmospheric air in the chamber or from that liberated from the saltpetre, and is thus converted gradually into sulphuric acid, and is afterwards absorbed by the water which covers the bottom of the chamber.

The first improvement, then, which I propose to effect is, an instantaneous union of the sulphurous acid gas with the oxygen of the atmosphere, and thereby save the constant expense of saltpetre, and also the great outlay of capital in the chambers where any great quantity of sulphuric acid can be manufactured by the gradual conversion of the sulphurous acid into the sulphuric acid.

The second improvement I propose to effect is, to effect a more perfect condensation of sulphuric acid when made by an improved mode of absorbing the same. The first improvement then, namely, the instantaneous union of sulphurous acid with the oxygen of the atmosphere, I effect by drawing them in proper proportions by the action of an air pump or other mechanical means through an ignited tube or tubes of platina, porcelain, or any other material not acted on when heated by the sulphurous acid gas. In the said tubes or tube I place fine platina wire or platina in any finely-divided state, and I heat them to a strong yellow heat, and by preference in the chamber of a reverberatory furnace; and I do affirm that sulphurous gas being made to pass with a sufficient supply of atmospheric air through tubes as described, properly heated and managed, will be instantly converted into sulphuric acid gas, which will be rapidly absorbed as soon as it comes in contact with water. The sulphurous acid gas I cause to be generated by the combustion of sulphur or pyrites, or any other metallic sulphuret, in a close oven, having one or more apertures for the admission of atmospheric air, and another aperture leading to or communicating with the aforesaid tubes. The relative proportions of sulphurous gas and atmospheric air are regulated by the size and working of the air pump, which must pump out at least eighty-five cubic feet of air for every pound avoirdupois of sulphur consumed.

My second improvement, namely, a more perfect condensation of the sulphuric acid when made, I effect thus:—I cause a chamber or chambers to be erected, of any size and materials that may be thought convenient, but by preference of silicious stone in a circular form, and about eight feet in diameter and thirty feet high. This I cause to be lined nearly or throughout with lead, to be filled nearly to the top with silicious pebbles, or any substance presenting an extensive surface, and not acted upon by the sulphuric acid. Upon the pebbles or other substances I place a sheet of lead, pierced with small holes, for the better distribution of the liquor to be hereafter mentioned. The chamber is to be domed over, and rendered air-tight on the outside, except by an opening on the top, through which a quantity of water or dilute acid is let in upon the pebbles to the height of about fourteen inches. A lead pump is fixed by the side of this chamber, drawing the liquor from its bottom, and emptying its contents into a lead funnel placed in and over the aforesaid opening in the top of the dome, and which said pump is kept constantly worked by a steam engine or any other power that may be preferred. The pipe of the funnel must be of such a size as always to keep some liquor in the funnel, and never to allow any air to pass down that way into the chamber; and the pump must throw a sufficient quantity of liquor to keep all or the greater part of the pebbles moistened. A pipe leading from the ignited tube or tubes, after passing through some water for the purpose of cooling it, terminates in this chamber just above the top of the liquor, while another pipe going off from the top of the chamber leads to the air pump, so that all the air charged with sulphuric acid has to pass through the bed of moistened pebbles, which have a constant supply of water or dilute acid continually passing down them. When the liquor is considered sufficiently charged, or when it will not absorb the sulphuric acid gas, which may be known by examining, the air discharged from the air pump is to be drawn off by a pipe and cock in the bottom of the chamber, and treated in the usual way.

Note, I do not claim a right to any mode by which sulphur or sulphurets may be converted directly into sulphuric acid by the action of heat or otherwise, if such method ever has been or ever shall be discovered; but I claim an exclusive right to any plan by which sulphurous gas and atmospheric air, either alone or mixed with any other gas or gases, shall be either forced or drawn by an air pump or any other mechanical means through an ignited tube or tubes.

I also claim the exclusive right to the use of platina in any finely-divided state, for the purpose of assisting the action of heat in combining sulphurous gas with oxygen in the manufacture of sulphuric acid.

I likewise claim an exclusive right to every mode by which chambers used in the manufacture of sulphuric acid can be charged with silicious pebbles or other substances for the purpose of exposing extensive surfaces, and which surfaces can be either constantly or occasionally moistened by the liquor pumped or drawn from below them.

IN WITNESS WHEREOF, I, the said PEREGRINE PHILLIPS, have hereunto set my hand and seal, this Fifteenth day of July, in the year of our Lord One thousand eight hundred and thirty-one.
PEREGRINE (L.S.) PHILLIPS, Junr.

Signed, sealed and delivered in the presence of
JAMES LIVETT, Solr., Bristol.
RICHD. HOWELL, His Clerk.

AND BE IT REMEMBERED that on the Fifteenth day of July, in the year of our Lord, 1831, the aforesaid Peregrine Phillips came before our said Lord the King in His Chancery, and acknowledged the Specification aforesaid, and all and every thing therein contained and specified, in form above written. And also the Specification aforesaid was stamped according to the tenor of the Statute made for that purpose.

Inrolled the Fourteenth day of September, in the year of our Lord One thousand eight hundred and thirty-one.

When we remember the time, and the absence of institutions for acquiring scientific knowledge, I think we may conclude that the author of the process had acquired a considerable amount of accurate information which he was able to apply to practical use. Moreover, this invention was no lucky or momentary inspiration. The knowledge displayed could only have been acquired by steady and continuous work.

Peregrine Phillips, jun., was a young man who had made good use of his youth in acquiring valuable knowledge. It is noteworthy that although nearly a hundred years have elapsed since this young Bristolian made his experiments and gradually improved his apparatus, yet the essential details are the same to-day as they were when first made known.

The necessary protection having been obtained by the grant of the patent, the next point to inquire about is as to the author's success in working the process. But here my records absolutely fail me. Both directories and newspapers give no information. We may therefore conclude that no works for making sulphuric acid by this process were established in Bristol. Moreover, the name of Peregrine Phillips, jun., disappears from every local record after 1831, and his late private residence is occupied by another. In all probability this means that directly after the dissolution of partnership in June, he left Bristol to seek his fortune elsewhere.

Possibly in that elsewhere he tried to work his invention, but probably without commercial success. This is not to be wondered at when we remember the large amount of plant employed in modern works using the method.

In these works engineering skill and chemical knowledge, which were not even thought of in 1831, are made to assist, and the combined results are highly satisfactory. But the poor inventor had none of these things, and his reward was probably nil. It was not until nearly fifty years after that the Badische Anilin und Soda Fabrik successfully worked the process on the large scale in Germany.

The youngest partner having left the vinegar business, its subsequent history is soon told. In the notice of dissolution quoted above it is stated that the business will in future be carried on under the name of Phillips and Thorne. But it did not last long. In 1831 the elder Phillips gave up his business of tailor and went to live at the vinegar works in Thomas Street. But in 1832 the works were abandoned. No notice of any bankruptcy can be traced, so we may conclude that trade had gradually declined so much that it was not worth while carrying on any longer.

In the *Bristol Journal* for October 5, 1832, appears the notice of a sale by auction on the premises, 48 Thomas Street, of the "entire vinegar plant, stock in trade, complete apparatus, &c. &c.," of the "late firm of Phillips and Thorne, they having dissolved partnership." Full details are given, and it is obvious that the works were fairly extensive and well equipped.

Immediately after this the father seems to have left Bristol, for no other record later than the date of this sale can be found. The name of Peregrine Phillips, either senior or junior, entirely disappears from Bristol records. Parish registers, as well as the official records, have been searched, but no notice of the deaths of either of our worthies can be discovered. Undoubtedly they left Bristol finally in 1832.

The discovery of Peregrine Phillips, jun., was undoubtedly of first-rate importance, and the young man must have been of far more than ordinary intelligence; yet it is quite easy, if not probable, that the history recorded above reveals a note of tragedy. As thus: Peregrine the elder was probably an industrious and prosperous tradesman, and was making a good income. He was blest with a clever son whose future was dear to him. Money was freely spent on his son's education, and when he became of age the savings of his father were used to start him in a business of far greater possibilities than that in which his father had done so well. So great was the father's confidence in his son's ability that he left the conduct of the business to him and his partner whilst he himself continued to work at his trade in Milk Street. But the genius of the son was not suited to the humdrum of business details. He was experimenting on bigger things than vinegar making, and as a result of his work he introduced the process which has benefited succeeding generations but not himself. The result was inevitable. The business did not pay and a rupture ensued. The son left, and the old father, in order to save his money which he had invested in the business, gave up his tailoring to try to save his capital; but without much success. Possibly the old man, having lost most of his money, left the city where he had held an honourable position for so many years.

Seasonal Sunshine in Great Britain.

By Chas. Harding.

NEVER before has the good effect of sunshine on health been so fully recognised as it is now; the great benefit derived from sunshine by individuals of all ages, whether strong and robust, or weak and delicate, is being brought home to us in many ways. The records of sunshine by Campbell-Stokes' self-registering instruments are very satisfactory so far as registration is concerned, but compared with other meteorological elements such as pressure, temperature, and rainfall, they are of more recent date. Sunshine records were practically commenced in about 1881, but by ordinary observers they have been somewhat tardily used.

The "Book of Normals" published by the Meteorological Office, giving monthly normals for stations for the 35 years from 1881 to 1915, supplies the principal facts for comparisons here made. These on examination are found to contain comparatively few complete records for the 35 years; the majority of the stations are for shorter periods and are worked up to the 35-year period by comparison with adjacent stations. For the most part, only those stations are taken which have observations of sunshine for the complete period, so that the comparisons are more trustworthy than they would otherwise be.

Dealing first with the annual results, and comparing the records for the year in different parts of Great Britain, it is found that in Scotland there are five stations which yield an average annual duration of sunshine amounting to 3·41 hours a day; the most is 3·80 hours a day at Aberdeen; the least, 2·97 hours a day at Glasgow. In the south of England, taking Southampton, Falmouth, and Plymouth, the average annual duration is 4·65 hours a day, ranging from 4·56 hours at Plymouth to 4·82 hours at Falmouth. The excess in the south of England over Scotland amounts, on the average, to 1·24 hours a day for the year.

Comparing eastern and western districts, the stations in the eastern districts of England give an annual duration of 4·19 hours a day, while the western stations give 4·17 hours a day.

The central or Midland counties give an annual average duration of 3·90 hours a day—two of the three stations taken are Oxford and Cirencester, which give 4·13 hours a day, the agreement for the year and for the several seasons being remarkably similar.

Dealing with quarterly results of sunshine, dividing the year as generally recognised in meteorology, the winter quarter being represented by December, January, and February, and the summer quarter by June, July, and August. In the north of Scotland, as shown by the Orkneys and the Hebrides, there is little difference between the spring and summer sunshine; indeed, in the Orkneys the duration of sunshine is rather greater in the spring, the relative amounts being 4·60 hours a day in spring and 4·54 hours a day in the summer. For Scotland as a whole the average daily sunshine for the four quarters, starting with winter, is 1·34, 4·64, 5·02, and 2·60 hours; for the south of England the corresponding seasonal values are 2·08 hours a day, 5·78, 6·94, and 3·78 hours. The greatest gain for any season in the south of England is 1·92 hours a day in the summer season, and the least gain is 0·74 hours a day in the winter.

In the east of England the seasonal daily values are 1·85 hours in the winter, and in the following seasons 5·23, 6·26, and 3·40 hours; in the western district of England the corresponding values are 1·68 hours a day in the winter, followed in the other seasons by 5·46, 6·26, and 3·25 hours. The average daily duration of sunshine is thus less in the winter and autumn in the western district, including St. Ann's Head and Douglas in the Isle of Man, than in the eastern, absolutely the same in summer in both districts, but more in the western district in the spring.

In the central or Midland counties the seasonal sunshine records give for the winter 1·68 hours a day, and for the following seasons 4·88, 5·87, and 3·13 hours; these are less than for the east of England in all seasons, and are less than in the western districts except for the winter, when the two districts are in absolute agreement.

A later "Book of Normals" published by the Meteorological Office gives the weekly, monthly, quarterly, and seasonal normals for districts for periods ending with 1915. In all seasons the least sunshine occurs in the north of Scotland and the most in the English Channel. Comparing south-east England with south-west England and South Wales, the average sunshine for the year in south-east England is 4·49 hours a day, and in south-west England and south Wales, including the so-called Cornish Riviera, it is 4·28 hours. In the winter, south-east England has an average daily sunshine of 1·92 hours, and in south-west England and south Wales the value is 1·91 hours a day; in spring the hours of sunshine for the two districts are respectively 5·50 and 5·36; in summer 6·88 and 6·41, and in autumn 3·46 and 3·31 hours. In each season, therefore, the value for the eastern district is above that of the western.

The amounts of sunshine vary considerably in different years and in different seasons. A record of 40 years' sunshine at Oxford, from 1881-1920, shows that the highest total in any year is 1810 hours in 1899, and the least, 1158 hours in 1888. In the winter months the amounts range from 106 hours in February 1899 to 5 hours in December 1890; in spring from 294 hours in May 1909 to 62 hours in March 1916; in summer from 310 hours in July 1911 to 99 hours in July 1913; in autumn from 223 hours in September 1911 to 30 hours in November 1888.

For the corresponding 40 years at Greenwich Observatory the maximum hours of sunshine in any year is 1778 in 1911, and the least in any year is 1069 hours in 1888. The year 1921 had sunshine for 1761 hours, but this is after the 40-year period. In the years 1892–96 the records at Greenwich are doubtful, owing to the development of cloudiness in the glass sphere of the sunshine recorder, the glass having deteriorated; this suggests the need of great care at other stations at home and abroad. In the winter months the amounts range from 106 hours in February 1914 to 2 hours in December 1890; in spring from 326 hours in May 1909 to 46 hours in March 1888; in summer from 335 hours in July 1911 to 95 hours in August 1913; in autumn from 234 hours in September 1911 to 23 hours in November 1912.

In the abnormal summer of 1911, in the 18 weeks from the commencement of June to the end of September, there were 15 weeks with an excess of sunshine in England E., Midland Counties, England S.E., and England S.W.; 14 weeks in England N.E. and N.W.; 13 weeks in Scotland W. and in the English Channel. July was exceptionally bright; in the south of England the excess of sunshine was very great, averaging about 5 hours a day more than usual at some stations. Eastbourne and Hastings had 160 per cent. of the average; Greenwich and Kew Observatory, 161; Brighton, 163; Plymouth, 169; Torquay, 172; and Tunbridge Wells, 180 per cent. At Greenwich the duration was 335 hours, which is 110 hours more than the average; this was the brightest July since the commencement of sunshine records. The duration of bright sunshine at Greenwich for the four months June to September was 1053 hours, a higher total than in any previous year on record. In 1911 the duration of sunshine at Greenwich was 1778 hours; at Westminster, 1592 hours; and at Bunhill Row, in the heart of the City, 1444 hours, showing clearly the loss of sunshine in the metropolis; the loss is usually proportionately greater in the winter than in the summer. The duration of sunshine at Greenwich for the summer season June to August in 1911 was 819 hours, and the mean temperature for the three months was 66°·1, about 5° in excess of the normal.

The following shows the difference between a good and bad season for sunshine: The year 1903 was about the wettest year on record, certainly the wettest at Greenwich Observatory for the last hundred years. The summer rainfall at Greenwich, June to August, was 16·16 inches, and the duration of bright sunshine 560 hours; whereas in 1911 the duration of bright sunshine was 819 hours. Last year, 1925, was a dull and comparatively sunless summer; the total duration of sunshine in the three summer months was 587 hours, and the total rainfall was 6·10 inches. The year 1924 also had a dull summer; the total sunshine at Greenwich was 589 hours, and the rainfall was 8·49 inches. These summers were remarkably dull in comparison with 1911 and 1921.

However desirable it may seem to decide which part of England enjoys the longest duration of sunshine, it is not easy to determine the most sunny region, although the following results seem to give a preference to south-east England. The published records of the Meteorological Office available for 35 years, which enable a trustworthy comparison to be made, give results for fewer stations than seem desirable, and in years to come, as the periods increase, results will become more satisfactory.

The highest average annual duration of sunshine at any station for the period of 35 years, 1881 to 1915, is 4·92 hours a day at St. Leonards, in England S.E.; and the station with the next highest average annual duration is Falmouth, in the Cornish Riviera, with 4·82 hours a day. The seasonal values for the two stations are: St. Leonards in the winter 2·25 hours a day, and in the following seasons 6·01, 7·34, and 4·03 hours; at Falmouth in the winter 2·21 hours a day, and in the following seasons 6·01, 7·15, and 3·90 hours; St. Leonards having most sunshine at all seasons except in the spring, when the duration of bright sunshine is the same in both places.

Records for less than 35 years given in the Meteorological Office normals show that, after weighting with other stations near, Felixstowe in England E., with 11 years' observations, ranks highest for the year, with 5·04 hours a day, and with a summer average of 7·84 hours a day. Worthing, with 17 years' observations, has an annual average of 4·98 hours a day and a summer average of 7·42 hours a day. Eastbourne, with observations for 30 years, has an average annual duration of 4·88 hours a day and a summer average of 7·37 hours. All of these have a higher daily average sunshine than the Cornish Riviera.

A rough summary of sunshine observations such as that here given is far from satisfactory, and is drawn up for the most part on published data readily to hand. Without doubt there are many considerations of greater importance to the Meteorological Office and to the general public, but since there has been a great accumulation of sunshine observations over Great Britain in recent years, an official discussion bringing the normals up-to-date would be of considerable scientific interest and would, without doubt, be heartily welcomed.

News and Views.

General approval from scientific men and naturalists the world over will be extended to the Society for the Preservation of the Fauna of the Empire in its active propaganda against the indiscriminate and wholesale destruction of wild game as a means for the extermination of tsetse flies, and, therefore, of the diseases, both of human beings and stock, which they are the means of transmitting. Certain proposals to throw open game reserves in Zululand led to a deputation from the Society, headed by Dr. P. Chalmers Mitchell, to the High Commissioner for the Union of South Africa, to protest against this measure, and a report of its proceedings, together with a memorandum on the subject, printed in the December number of the Society's journal, will be read with great interest and sympathy. The Society urges that the indiscriminate slaughter of big game does not necessarily lead to the extermination of the tsetse-flies, but may have the result of leading the flies to seek other and smaller hosts, still more difficult to control, or failing a suitable wild host, to attack man himself The danger to the human population would, therefore, be increased rather than decreased, and, in the Mwanza district of the Tanganyika Territory, where wholesale game destruction due to military operations was followed by a serious epidemic of sleeping sickness, there would appear to be evidence in support of this view. The Society urges strongly a more scientific approach to the solution of the problem by detailed studies of each separate species of fly and host, and a painstaking survey of local conditions before any measures are adopted. It points to the success which has been achieved in Tanganyika Territory by systematic attack on the important bush elements by the native population and by organised late grass-burning as measures for controlling the breeding-places of the flies, and pleads for further trial of such methods in Zululand. It agrees that discriminate control of wild game would probably help in the final solution of the problem.

MR. SAMUEL AUGUSTINE COURTAULD has given 30,000*l.* to the Middlesex Hospital Medical School, London, to found an Institute of Biochemistry. The new building will be in the precincts of the Hospital, and will probably consist of seven storeys, the upper five of which will be devoted to all branches of biochemistry. The Hospital has endeavoured to develop the study of this subject during the past years, with the result that the size of the work has outgrown the existing accommodation. At the present time chemical physiology, chemical pathology, and the chemical routine work for the Hospital patients, together with the more purely chemical investigations of natural products, are dealt with in the same department. This has necessitated the acquiring of a series of scattered laboratories and of occupying rooms in the Bland-Sutton Institute of Pathology.

MR. COURTAULD's gift will enable the Middlesex Hospital to constitute a compact department of much greater size, in which all the above-mentioned branches of study can be pursued. Workers in the new institute, however, will still retain the privilege of close co-operation with the Bland-Sutton Institute of Pathology, and with the clinical staff of the Hospital, and thus the new institute will be in rather a unique position. The constant passage of routine work through such a department will focus the attention upon the clinical and therapeutic aspect of biochemistry. Although the plans of the new department, which will be called the S. A. Courtauld Institute of Biochemistry, have not yet been definitely decided upon, it is proposed to make ample provision for the teaching of both chemical physiology and chemical pathology. A large laboratory for the more organic chemical side of the work will be included, together with accommodation for the pharmacological testing of chemo-therapeutic substances. Mr. Courtauld's very generous gift will enable the Hospital to continue its support of this very valuable line of teaching and research.

A RECENT announcement made in the Legislative Assembly at Delhi by Mr. J. W. Bhore, the Secretary of the Department of Education, Health and Lands, is of considerable interest since it brings to an end a period of uncertainty as to the future position both of research and education in forestry in India. It will be remembered that the Forest Research Institute at Dehra Dun was inaugurated in 1906, the Forest School being given the status of a College. A two-year course for the training of the Provincial Service was afterwards instituted, the courses previously given being for the subordinate staff only. In 1914 the Research Institute building was opened. The War made considerable demands upon the Institute, and the research work carried out there, especially in utilisation, was of material importance to the country. By 1919 it was apparent that the research work had already outgrown the block of buildings erected in 1914. The value of this work was fully appreciated by the Government of India, and a scheme was drawn up for the erection of a new Research Institute on a far larger scale, land being acquired for the purpose. A check was given to the development of the new scheme owing to the recommendations of the Inchcape Retrenchment Committee. The Institute was placed on a block grant for three years. Mr. Bhore now announces that the Government of India has sanctioned the whole grant for the new buildings. He also states that the training of the Indian probationers for the Imperial Forest Service will in future be undertaken at Dehra Dun; a two-year diploma course will be given there, the old Research Institute building of 1914 being converted for this purpose. It is perhaps a little sanguine to hope that the training at Dehra will be as good as that given at the universities of Great Britain, but the experiment will be watched with interest.

SIR FREDERICK GOWLAND HOPKINS presided on March 13 over a dinner of the Biochemical Society held at the Grosvenor Hotel, London, to celebrate the hundredth meeting of the Society. In proposing "The Society" he traced the change of opinion concerning bio-chemistry, which has taken place since he went to Cambridge thirty years ago, and was informed that bio-chemistry was not biology and certainly not chemistry. After paying a tribute to Mr. J. A. Gardner and Prof. R. H. A. Plimmer in inaugurating the Society, he directed attention to its constantly accelerating progress, remarking that only one plateau has appeared in the curve of membership, and that was during the years 1914–18. Biochemists, he said, are highly privileged persons, because many of them are brought into close contact with agriculture and other vitally important industries. They need, however, encyclopedic knowledge, because they never know from what source they may derive information of vital importance. Describing the genesis of the Society, Mr. Gardner explained his indignation one morning in 1911 on learning in the daily press that an Austrian was to be sent over to England to teach British workers how to apply chemistry to living tissues. In response to post-cards sent out by Prof. Plimmer and himself, thirty-two bio-chemists attended a meeting and the Society was founded Prof. Harden spoke of the keenness of members; in the Chemical Society, he said, there is one paper to every ten members, but in the Biochemical Society there is one paper to every three members. Prof. E. H. Starling proposed the health of Sir Frederick Hopkins. Characterising him as the leader of the school of British bio-chemistry, he said that he differs from most workers in being a natural historian as well as a trained chemist. In his work there is no such thing as an unconsidered trifle. He referred also to the bearing that his appreciation of colour has had on his researches.

THE Bureau of Chemical Abstracts, which now issues the *British Chemical Abstracts* for the Chemical Society and the Society of Chemical Industry, is endeavouring to secure uniformity in the method of referring to original papers. It issues to its abstractors a pamphlet of instructions as to what information the abstracts should contain, the use of the terminations *ous* and *ic*, the distinction between hydroxides and hydrates, and the restriction of *ol* to alcohols, the other *ols* to become *oles*. A list of recognised abbreviations and symbols is also given. Of the great need of more uniformity in the nomenclature and notation of chemistry there can be no doubt, and in these matters the views of the Bureau will have great weight, but on questions common to all sciences the views of other bodies publishing abstracts at home and abroad must be considered. The Chemical Bureau advocates the order: title, author, journal, year, volume, page in abstracts or references, while the more common practice is to give the year last. For dates it uses (p. 4) '25.6.23,' but does not indicate whether the year is the first or the last number given, and astronomers would understand 1925.6.23. Although the method of writing the time of an event is not one of the points dealt with in the instructions, and one might write 5.30 P.M. June 23, 1925, without being considered unmethodical, the astronomer's logical 1925, June 23, 17h. 30m. has much in its favour.

NEAR Quetta in British Baluchistan, Dr. C. G. Abbot, assistant secretary of the Smithsonian Institution of Washington, D.C., and Director of the Smithsonian Astrophysical Observatory, has found the most suitable site that he has seen thus far in his search of the eastern hemisphere for a place to locate a new solar observation station. This new station, to be erected by the Smithsonian Institution with funds provided by the National Geographic Society, will be the third under the direction of the Smithsonian Institution making daily observations of the variable radiation of the sun, the other two being located in Chile and California. This third station will furnish a needed check on the values from the other two, providing a more dependable daily value of the solar constant. It is hoped that accurate long-range weather forecasting may become possible as a result of this fundamental work by the Smithsonian Institution. Dr Abbot has visited the Sahara and India and now is on his way to south-western Africa.

IN his discourse at the Royal Institution on Friday evening, March 12, Sir J. J. Thomson, Master of Trinity College, Cambridge, observed that the brilliance of the electric discharge has long been known, and exemplified in its greatest brilliancy in lightning and the aurora; but the subject of his lecture was confined to the radiation from electric discharges through gases in tubes of various forms. The radiation from Röntgen rays and other kinds of radiation inside tubes cannot get out. Evidence of the existence of radiation in these tubes can be obtained by means of the luminescence discovered by Wiedeman; it can be located by shadows, or its effects shown by ionisation (Hoffmann). The radiation from electric discharges can be observed and measured by the use of films of various substances inside the tube, showing the photo-electric effect. By using aluminium and celluloid screens with the tube, the absorption of radiation can be shown. The stream of negative and positive particles can readily be demonstrated by reversing the current. There were elaborate experiments shown during the course of the lecture by means of alternating currents and the use of reflectors within the tubes: in one case a magnificent ring of light appeared in the tube.

THE Department of Scientific and Industrial Research has recently established a small research laboratory in the vicinity of Covent Garden fruit and vegetable market. The laboratory will work in close connexion with the Low Temperature Research Station, Cambridge, which is the headquarters of the fruit and vegetables section of the Department's organisation for food investigation. Problems which are beyond the resources of the laboratory can therefore be handed on to the Station without delay. The object of the laboratory is to bring the Low Temperature Research Station into closer contact with the trade in fruit and vegetables, and with the practical aspects of the problems of their transport and storage. Covent Garden has been selected as the most suitable situation for the Laboratory because fruit and vegetables can be studied there at all times of the year; because its supplies are derived from all quarters; and because it is a convenient centre from which to reach the main producing areas in England, and the chief ports to which supplies are brought from overseas. The address of the Laboratory is: The Covent Garden Laboratory, Dudley House, Endell Street, London, W.C.2.

THE December issue of *Isis* contains the seventeenth Critical Bibliography of the History and Philosophy of Science and of the History of Civilisation. The original conception of this extremely useful annual bibliography was due to Dr. George Sarton, who continues to edit it, although the journal *Isis* itself is now published by the History of Science Society. In the present bibliography there are no less than 482 items, a fact which speaks well for the progress of what the Bishop of Birmingham recently referred to as the new humanism. The entries are systematically arranged, so that scholars interested in a particular subject or period can gather the information they require with very little trouble. The more important items are provided with short descriptive notices, generally from the pen of the editor himself, but occasionally written by experts on the subject under consideration. Of all the features of *Isis*, we regard these critical bibliographies as among the most valuable; they are, indeed, unique and indispensable. The useful bibliography given by Prof. Aldo Mieli in the *Archivio di Storia della Scienza* deals practically entirely with Italian work, while the *Mitteilungen zur Geschichte der Medizin und der Naturwissenschaften* does not cast its net nearly so widely as the indefatigable Dr. Sarton. Readers of NATURE who wish to support the invaluable work which *Isis* is doing should write to Dr. Frederick E. Brasch, secretary of the History of Science Society, Smithsonian Division, Library of Congress, Washington, D.C., U.S.A.

A PAMPHLET of nineteen pages from the Geological Survey of China includes a useful summary of the progress of the Survey under four heads, namely: (1) Ten years' work of the National Geological Survey of China; (2) Provisional programme of "Palæontologia Sinica"; (3) Memorandum on the establishment of museums in Peking; (4) Memorandum on the extension and rebuilding of the Geological Museum. The first section includes an index map showing the areas of China which have been geologically surveyed and of which a geological map on the scale of 1 : 1,000,000 has been prepared; the first sheet has been issued, and four others are in the press. The Survey Library was mainly established at the cost of 40,000 dollars subscribed by the mining companies and private donors. The Geological Survey was allotted in 1916 an annual grant of 80,000 dollars, but the amount received has fallen to 20,000 dollars, and the work has been carried on through the self-sacrifice of the members of the Survey. The list of the Survey publications shows an output of work which is highly creditable in consideration of the political and financial embarrassments of the past few years. A memorandum by Dr. Gunnar Andersson announces the proposed establishment of a Biological Museum at Peking of the same standard as the Geological Museum; the ideal is a group of museums, each organised as an institute for scientific research combined with an educational exhibition.

THE weather in the British Isles for the winter season ending February 27 is dealt with in the *Weekly Weather Report*, published by the Meteorological Office from observations during the months of December, January, and February. District values and their deviations from the normals are given for eleven districts of the British Isles, together with the mean values for the whole. Mean temperature was highest in the Channel Islands, where it was 46°·2 F., and lowest in the east of Scotland, where the mean was 37°·5; in the south-east of England, including London, the mean was 41°·7. Mean temperature for the winter was above the normal in all districts except in the east of Scotland, where the deficiency was 0°·1. The greatest excess over the normal was 1°·4 in the north of Ireland, and the next highest excesses were 1°·3 in the south-east of England and 1°·2 in the east of England. The absolutely highest temperature was 60° in the north-east of England, varying to 55° in the west of Scotland; the lowest was 4° in the east of England, ranging to 18° in the south of Ireland and 28° in the Channel Islands. Rainy days were in excess of the normal in all districts; the greatest excess was 10 days in the east of Scotland. The aggregate amount of rain was in excess in all districts except in the north of Scotland, where the deficiency was 1·77 in., the greatest excess was 3·78 in. in the Channel Islands, while in the south-east of England the excess was 2·25 in. There was a slight deficiency of sunshine in all districts except in the south-east of England, where there was an excess of 0·1 hour a day on the normal, and the average duration of sunshine, which for the winter was 1·9 hours a day, was greater than in any other district except the Channel Islands, where it was 2·1 hours a day.

THE recently issued part of *Curtis's Botanical Magazine* (Part ii. of Vol. 151) contains eleven plates, most of them "L. Snelling del et lith," which worthily maintain the high standard appropriate to the present editor, Dr. O. Stapf. In the *Journal of the Royal Horticultural Society*, Vol. 51, Part i., January 1926, Dr. Stapf has a very vivid and forceful account of the history of this famous magazine, commenced in 1787 by William Curtis, as an illustrated magazine, to issue to subscribers to his garden at Lambeth Marsh and other interested patrons, and incidentally to retrieve his financial losses upon a monumental and far too expensive "Flora Londinensis." Dr. Stapf traces the history of the magazine through its various vicissitudes, its triumphal career under the Hookers, father and son, its association with Kew when Sir William Hooker became Director of the Royal Botanic Garden, and its submergence during the difficult years following the War. This history is a timely reminder to the fellows of the Royal Horticultural Society of the fine tradition of this magazine and the purpose it serves, as it is now edited by Dr. Stapf for the Society, which has undertaken responsibility for the new issue, and in so doing promoted the interests both of botany and horticulture. Incidentally the current issue illustrates by the proverbial exception the general rule as to its contents. The magazine illustrates, not native plants, but plants introduced to British gardens from all parts of the world, the illustrations being accompanied by authoritative and very valuable systematic descriptions, with notes on the distribution of the plant and its cultivation in Great Britain. In the present number, however, appears a British plant, *Aconitum anglicum*, Stapf, a new species which the editor creates for a monkshood often grown in English gardens, but also found wild in England. Dr. Stapf has failed to trace it outside England and is forced to the conclusion that it is truly native.

WE much regret to announce the death, on March 15, at the age of seventy-nine years, of Sir Philip Watts, K.C.B., F.R.S., lately Director of Naval Construction, Admiralty.

THE seventh Mackenzie Davidson Memorial Lecture of the Röntgen Society will be delivered by Dr. A. Dauvillier of Paris. Particulars of the subject and date will be given later.

SIR ARTHUR SMITH WOODWARD has left England for Beirut, Syria, where he will be engaged for the next three months in the preparation of a work on the Cretaceous fishes of Mount Lebanon.

AT the meeting of British botanists held in the rooms of the Linnean Society of London on March 10, it was resolved to send an invitation to the members of the fourth International Botanical Congress (Congress of Plant Sciences) meeting at Ithaca, New York, U.S.A., in August, 1926, to meet for the fifth International Botanical Congress, in London, in 1930.

THE Council of the British Association will nominate Sir Arthur Keith, Hunterian professor in the Royal College of Surgeons and secretary of the Royal Institution, as president of the Association for the meeting in Leeds in 1927. The presidency of Section K (Botany) at the Oxford meeting, made vacant by the death of Dr. William Bateson, will be filled by Prof F. O. Bower, formerly Regius professor of botany in the University of Glasgow.

THE New Museums Club, an association of University employees at Cambridge, is organising a popular scientific exhibition to be held in the University Examination Hall and the new wing of the Chemical Laboratory on March 24-27. The entire proceeds are to be given to the benevolent fund of the University Servants' Pension Scheme. The exhibition will be arranged with the view of giving a popular idea of the teaching of science and the scope of research in the University, and three lectures are to be given each day by different members of the University staff, including the vice-chancellor, Prof. A. C. Seward, who will describe " A Trip to Australia."

AT the annual general meeting of the Ray Society held on March 11, the following officers were re-elected: *President*, Prof. W. C. McIntosh; *Treasurer*, Sir Sidney F. Harmer; *Secretary*, Dr. W. T. Calman. Mr. C. D. Soar was elected a vice-president, and Mr. J. M. Offord and Mr. E. Whitley were elected new members of council It was announced that Prof. von Goebel's "Wilhelm Hofmeister: the Work and Life of a Nineteenth Century Botanist," translated by Mr. H. M. Bower and edited by Prof. F. O. Bower, would shortly be published, and that the Society's issue for 1926 would be the second volume of " British Hydracarina," by Mr. C. D. Soar and Mr. W. Williamson.

THE following have been elected officers of the Physical Society for the year 1926–27: *President*, Prof. O. W. Richardson; *Vice-Presidents*, Sir Oliver Lodge, Sir Richard Glazebrook, Dr. C. Chree, Prof. H. L. Callendar, Sir Arthur Schuster, Sir J. J. Thomson, Mr. C. Vernon Boys, Prof. C. H. Lees, Sir William Bragg, Dr. Alexander Russell, Mr. F. E. Smith, Dr. E. H. Rayner, Dr. J. H. Vincent, Dr. D. Owen, Prof. F. L. Hopwood; *Secretaries*, Prof. A. O. Rankine, Imperial College of Science and Technology, Mr. J. Guild, National Physical Laboratory, Teddington, Middlesex; *Foreign Secretary*, Sir Arthur Schuster; *Treasurer*, Mr. R. S. Whipple, 45 Grosvenor Place, S.W.1; *Librarian*, Mr. J. H. Brinkworth. Prof. Charles Fabry, professor of physics at the Sorbonne, has been elected an honorary fellow of the Physical Society.

A LENGTHY catalogue (New Series LX.) of new and second-hand books and periodicals on zoology and biology has just reached us from Messrs. G. E. Stechert and Co., 31 East 10th Street, New York. The prices asked, in American currency, appear to be reasonable.

MESSRS. Longmans, Green and Co., Ltd., will shortly publish a new work by Sir Jagadis Chunder Bose on " The Nervous Mechanism in Plants." A further volume is to follow. Another forthcoming book in Messrs. Longmans' list is "A Manual of the Flowering Plants and Ferns of the Transvaal with Swaziland, South Africa," by Dr. J. Burtt Davy, in four parts; Part I.—Pteridophyta to Bombacaceæ. The four parts when completed will be issued in one volume.

MESSRS. Dulau and Co., Ltd., 34 Margaret Street, W.1., have just issued a catalogue (No. 139) which should be of interest to many readers of NATURE. It gives the titles of nearly 1400 second-hand works relating to astronomy, astrophysics, and the industrial arts, many from the library of the late Dr. W. H. Maw. Copies are to be had upon application.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant inspector for the examination of laboratory and general scientific instruments under the India Store Department—The Director-General, India Store Department, Belvedere Road, S.E.1 (March 30) A professor of anatomy at the Ceylon Medical College, Colombo—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1 (March 31). An assistant pathologist under the Metropolitan Asylums Board—The Clerk, Metropolitan Asylums Board, Victoria Embankment, E.C.4 (April 1). An investigator under the Safety in Mines Research Board to carry out work on the strengths of materials and structures for the support of underground workings in coal mines—The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (April 6). A mycologist for the Forest Research Institute, Dehra Dun, United Provinces, India—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (April 7). A science master at the Lord Wandsworth Agricultural College, Long Sutton, Basingstoke—The Secretary, Lord Wandsworth College Trustees, 71 Piccadilly, W.1. A head of the department of hygiene and bacteriology and part-time lecturer in hygiene and maternity and child welfare at King's College for Women (Household and Social Science Department); also a part-time lecturer in economics—The Secretary, Campden Hill Road, W.8. An assistant lecturer in hygiene and public health at Battersea Polytechnic—The Principal.

Our Astronomical Column.

AURORAL DISPLAY OF MARCH 9.—A display of the Aurora Borealis causing widespread interest was seen from a number of places in the south and east of England during the evening of March 9, between half-past seven and half-past eight. It was visible, at least partially, from the suburbs of London, its probable commencement being noted by two members of the staff at Greenwich Observatory at $19^h 30^m$. Communications we have received from Mr. R. T. Gunther of Oxford and Mr. C. Leaf of Cambridge give interesting details of the rapid changes invariably associated with this phenomenon.

As seen from Greenwich, with the glare of the lights of east London to the north of the Observatory, the aurora appeared between $19^h 30^m$ and 20^h as a changing and indefinite area of suffused light, of a dull flame colour in the north-west and for a short time in the north-east sky. At Cambridge and Oxford a number of variable bands and streamers were visible, being at first white or greenish in the north and reddish in the north-west. Immediately after 20^h, Mr. Leaf states: "The pink colouration [of the streamers] became very strong, changing to a dark but intensely luminous red. At the same time the red streamers became a luminous patch which rapidly spread across the sky through north to east. At the western end of this band was a vast red patch which, starting at the horizon, reached almost to the zenith forming a most beautiful spectacle."

Mr. Denning, writing from Bristol, states that at $19^h 30^m$ an intense red glow was diffused along the northern horizon. This quickly faded and then rapidly increased in brightness, streamers developing at 20^h. "In the north-west . . . a broad column of white light 4° in width and apparently double became exceedingly conspicuous. It immediately widened until it consisted of a mass of rays 20° in width and the colour changed to an intense red."

An examination of the magnetograph traces at Greenwich shows that the magnets began to be noticeably disturbed at $19^h 30^m$, and at $20^h 5^m$ the Declination magnet was suddenly deflected 35′ towards the east. The magnet recovered its normal position by about 21^h, but it continued to show minor disturbance until the following morning. At the time, a large group of sunspots (see NATURE, March 6 and February 27) was very near the sun's west limb. There was, however, no large spot near the central meridian, although one of comparatively minor importance was slightly east of the meridian, in latitude 21° north, in a part of the sun not active in spots recently.

ENSOR'S COMET.—There is abundant evidence that Ensor's comet is now much fainter than was expected from its appearance in the southern hemisphere in January. It has evidently expanded greatly since perihelion passage, and now fills the whole of an ordinary telescopic field, so that the lack of contrast makes visual observation very difficult.

Mr. B. M. Peek, of Herne Bay, obtained a photograph on Wednesday morning, March 10, which shows a large faint nebulous blur so close to the tabular position of the comet that identity with it is probable. It may be recalled that Holmes's Comet in 1892 underwent a similar expansion which rendered it unobservable for a time. There was then a recrudescence of brightness at the nucleus, which later expanded again. The possibility of similar changes in the present case should be borne in mind. As the comet is now becoming circumpolar, it is well placed for observation. The following ephemeris is for 6 A.M.

		R.A.	N. Decl.	log r.	log Δ.

NEPTUNE'S SATELLITE.—A paper by Prof. Eichelberger, Director of the American Nautical Almanac, was read at the meeting of the Royal Astronomical Society on March 12, in which all the observations of Neptune's satellite from its discovery until the year 1923 were discussed. The work was commenced by Prof. Newcomb, but left unfinished at his death; his computations were utilised, but they have been greatly added to. A splendid series of observations by Prof. Barnard extending over twenty-five years deserves special mention. The period of revolution of the pole of the satellite's orbit about Neptune's north pole is found to be 585 years. The eccentricity of the orbit is very small, about 0·0049, but its reality appears to be shown by the fact that, when the observations are grouped by observers, each series indicates motion of the apse in the same direction, this being the opposite direction to that of the node, as it should be. The values found for the annual motion of the apse vary from 1·5° to 3·0°, but are very uncertain.

Dr. Jackson used Prof. Eichelberger's results to obtain an estimate of the period of Neptune's rotation. On certain assumptions as to the distribution of matter within the planet, he found the period 19^h; but he thought it quite possible that the true period was double the $7^h 50^m$ announced by Maxwell Hall from photometric observations, and afterwards supported by Opik and Liviander at Tartu.

THE DISTRIBUTION OF NON-GALACTIC NEBULÆ.—Some years ago a series of photographs of selected areas were taken by Fath for the purpose of the Mount Wilson Catalogue of Magnitudes. The limits of magnitude photographed were so low as 18 to 19 on the international scale, and counts were made of the nebulæ found in each area. These counts are re-examined by F. H. Seares in the *Astrophysical Journal*, vol. 62, p. 168. The selected areas are 139 in number, distributed at intervals down to 15° South Declination, and are arranged by Seares first to show the distribution of the nebulæ in galactic latitude. The diagram shows the gradual appearance of nebulæ at about 20° latitude (in both hemispheres), followed by a rapid increase in numbers up to 30°. The well-known concentration near the galactic poles is shown in the case of the North Pole, but the south polar region is not included among the selected areas. The distribution in galactic longitude is interesting in showing strong evidence of a band of nebular concentration crossing the North Pole in longitudes 50°-220°. It appears, however, that the distribution in longitude depends on the size of the nebulæ under consideration. The majority of those discussed by Seares are very small, having diameters of less than 30″. An estimate is made (after allowing for losses arising from aberration) of the total number of nebulæ in the sky. This number (estimated at 300,000) is considerably smaller than that given by Curtis (722,000); and though there is a source of error in the asymmetrical distribution of the photographs, Seares considers that it is insufficient to reconcile the considerable discrepancy between his estimate and that of Curtis.

Research Items.

The Aurignacian Station at La Quina (Charente).—In the *Bulletin of the Société d'Anthropologie de Paris*, Ser. 7, T. 6, Fasc. 1-3, Dr. Henri Martin gives an account of the Aurignacian levels of the well-known site of La Quina, where he has been engaged in systematic exploration since 1908. Although the site was brought to the notice of archæologists in 1884, when Dr. Martin first visited it in 1905 he could find no trace of any attempt at systematic or scientific investigation outside the excavations made in the course of the original road-making operations. Dr. Martin's investigations have revealed that the area of occupation was situated at the base of the cliff. The Aurignacian levels, three in number and superimposed, are on material brought down by land-slides, beneath which at the bottom is a Mousterian station. Over this station the debris formed a mound four metres thick and forty metres in extent, separated from the cliff by a hollow ditch in which was found the refuse of the earliest Aurignacian settlement, consisting of broken bones, in particular those of the reindeer and the horse, calcined stones and relics, broken and whole, of the industries of the inhabitants. On each of the occupation levels were layers of fallen material similar to that overlying the Mousterian and separating the stations one from another. Of the Aurignacian levels, the first or lowest and the third are the most important. The absence of audi points and of transitional forms in the lowest station showed that a certain development in culture had already been attained. The characteristic form is a reindeer horn assegai or lance head, flattened, but not quite conformable to the usual type. No graves were found and no example of artistic activity has come to light. The station belongs to the Lower Middle Aurignacian, and is comparable to Isturitz The middle station contains no specially characteristic features, and occupation was probably not prolonged. In the uppermost level of occupation the characteristic implement is the keeled scraper, and its culture is comparable with that of the Boulton site.

Buddermokan.—In the *Indian Antiquary* for February, Sir Richard Temple publishes the first part of some notes of investigations made some years ago into the question of a seamen's spirit of which the shrines, known to Europeans as Buddhamakam, are found along the coast of Burma from Akyab to Mergui. These shrines have no connexion with Buddhism. They are universal, being accepted by Buddhists, Hindus, and Mohammedans alike, and by natives of India, Burma, and China, a sign that they are symbols of the animism which underlies all Indian religions. Their chief votaries are sailors, fishermen, and those who obtain a livelihood by the water The name is Indian, not Burmese, and Mohammedan in origin. It is properly the shrine of Badar--Badarmaqâm, who is Pir Badar of Chittagong, known to Indian Mohammedans as Badru 'ddin Auliâ, who represents by his attributes Khwâja Khizar in modern Bengal. Khwâja Khizar in turn is Al-khidhr of the Koran, whose legend is mixed up with Mehtar Ilyâs, the prophet Elias of Jewish tradition, the Spirit of the Flood. This form of belief is still extant in Russia and finds expression in the water festival of the prophet Ilyâ. So far as the evidence obtained from Burma goes, it appears that at certain spots along the Burmese coast, at Akyat, Sandoway, and Mergui, a supernatural being is worshipped, his worship being mainly that common all over the east, *i.e.* it is a survival of a local animistic worship. Its connexion with Pir Badar is due to the fact that, as often happens, one of the local professed religions, in this case the Mohammedan, has annexed the supernatural being of the older belief and has identified it with the saint best known to the bulk of the sea-faring population, Pir Badar of Chittagong.

The Systematic Characters of Sea-Gulls.—There is a freshness of treatment and wealth of observation in Dr. J. Dwight's monograph of the world's gulls which make it invaluable to the systematist (*Bulletin of the American Museum of Natural History*, Dec. 31, 1925). Difficulties in the determination of species have always been involved in the complicated series of plumages gulls pass through before attaining finality, which vary from the two-year plumage-cycle of the small gulls to the four-year cycle of the large species, each year having its own non-nuptial and nuptial arrangements Consequently great attention has been paid by Dr. Dwight to the discrimination of the stages of immaturity, with the result that the description of a species, say the lesser black-backed gull, expands into an account of ten different stages of plumage, which, with an abbreviated synonymy, accounts of distribution and of the four geographical races, cover nine pages of print. The succession of changes is made readily intelligible by excellent diagrams of the colour patterns of the wings and tail of every species in every plumage, and the flesh colours of bills and feet of many species are accurately portrayed. Single type specimens no longer meet the needs of this detailed analysis of stages, so that a series of "reference specimens" is appended to each plumage. The author has examined each of the forty-four known species of gulls, and his classification remains conservative, though he creates a new sub-genus Saundersia for a Chinese species of Hydrocoloeus.

Canadian Salmon.—There have as yet been no published records of the examination of scales from Canadian salmon: Mr. Menzies' paper on the salmon (*Salmo salar*) from the River Moisie, flowing into the north side of the Gulf of St. Lawrence (*Proc. Roy. Soc. Edinburgh*, vol. 45, Pt. iv. No. 30), is welcome, therefore, as giving the first information on the life-history of the Canadian fish furnished by scale-readings. Unfortunately, the samples collected for Mr. Menzies for examination were small and cannot, as he admits, be considered as representative of the salmon population frequenting the river. The scale-markings resemble exactly those of the scales of Scottish fish: the period of slow growth is well-marked. Scales taken from fish in June and early July showed that 81 per cent. were 'spring' fish; in Scotland at this period one expects clean-run fish to be almost exclusively 'summer' fish. The majority were 'maiden' salmon returning from the sea after three winters. Grilse were absent from the sample. The spawning-scar, when it occurred, was clear and showed that 16·7 per cent. were spawned fish, as compared with the usual 4 per cent. on the east coast of Scotland; most had spawned once, but the numbers with two and three spawning rings were noteworthy; one even was returning to spawn a fifth time. The average age of the smolts at migration was between that of smolts from the north-east of Scotland and smolts from Norway. The three-winters fish were fat and well nourished, comparing favourably with the most finely shaped Scottish fish. Length calculations from scale measurements did not differ materially from those of Scottish salmon.

A PECULIAR PARASITIC CRUSTACEAN.—Prof. T. Komai describes (*Mem. Coll. Sci., Kyoto Imp. Univ.*, vol. 1, No. 3, Oct. 1924) a new species of Sarcotaces, fourteen examples of which were found embedded in the subdermal connective tissue of Antennarius. Their presence causes prominent lumps on the surface of the fish. Each individual is enclosed in a thin sac formed of the host's connective tissue, and the sac has no opening to the exterior. The parasite, which varies in length from 5 mm. to 15 mm., is rounded anteriorly and pointed posteriorly, and exhibits eleven segments, the first six of which constitute the cephalic and thoracic region and the last five the abdomen. In the first segment is a small mouth bordered on each side by a hand-shaped process—possibly the maxilla. Farther back is another pair of processes—possibly the vestigial maxillipeds. There are no antennæ and no limbs. The mouth leads into a blindly ending gut which contains dark particles, apparently the coagulated blood of the host, intermixed with muscular and connective tissue fibres. The ovary is freely branched; the oviduct arises in the sixth segment and opens near the anterior margin of the seventh, but continues backwards round the blind end of the alimentary sac and unites with the corresponding oviduct of the other side. On each side in the lateral region of the second segment is a testis, the lumen of which is continuous with that of a neighbouring branch of the ovary. In the fluid which fills the space between the body and the enveloping sac were found numerous developing eggs and free nauplius larvæ. The two previous observers—Olsson and Hjort—who have investigated Sarcotaces, placed it respectively in the Copepoda and in the Cirripedia. Prof. Komai agrees with Olsson's view, because the opening of the oviduct is in the first abdominal segment, and in the nauplius anterolateral and anal spines are absent. The two previously known species of Sarcotaces were obtained from fishes taken off the West Indies and off Norway. The present species is regarded as new (*S. pacificus*)

INFLUENCE OF ROOTS OF WALNUT TREES UPON OTHER PLANTS.—A. B. Massey has an interesting paper upon this subject in *Phytopathology* for December 1925 (vol. 15, pp. 773-784). He gives very convincing evidence that the presence of the roots of walnut trees in close contact with the roots of lucerne, tomato, and potato is responsible for the wilting and death of these other plants. The effect does not spread from the walnut tree roots generally into the soil, and is only produced when the walnut roots lie in close contact with the root system of the other plant. An extract of the bark of the walnut root is shown to have a toxic action upon the roots of, the tomato plant grown in water culture, and it is suggested, but not experimentally established, that the action of the walnut roots is produced by a toxic constituent substance, juglone, which is a naphthaquinone.

TREATMENT OF GRAIN FOR BUNT.—The treatment of bunt (caused by *Tilletia tritici* and *T. lævis*) with solutions of copper sulphate on formalin, as is usual, is open to the objections that the wheat seed has to be dried before sowing, and that care is needed to avoid the use of too strong solutions, which would injure the grain. Experiments on dry treatment with copper dusts have given very satisfactory comparative results, bunt being controlled, though not completely eliminated, by the use of such dusts (K. Sampson and D. W. Davies, *Welsh Journ. Agric.*, 2, 1925). The most successful applications were dehydrated copper sulphate and copper carbonate containing 50 per cent. copper, at the rate of 2 oz. per bushel of grain, other dusts with lower percentages of copper proving effective at ·4 oz. per bushel. On the whole, copper dusts were more efficient than formalin solutions, and had the advantage of eliminating risk of damage to the seed. The treated seed gave better growth in the field, with increased tillering and higher yield of grain, indicating that *Tilletia tritici* has some deleterious action on the plant apart from that caused by the replacement of healthy grain by bunted grain. The possibility exists of some stimulating action by the chemicals employed, and this is being investigated. The advantages of dry treatment lie in its convenience, as no solutions need making up, the grain is more easily handled at sowing time, and the dusting can be carried out at any time between harvest and sowing without danger of lowering the germination capacity of the seed.

INVESTIGATIONS ON POTATO DISEASES.—The growing importance of research on virus diseases entails constant seeking for new methods of investigation, of which some of the more recently devised are described by P. A. Murphy and R. McKay (*Sci. Proc. Roy. Soc. Dublin*, vol. 18, January 1926). Investigations are much hampered by the usual necessity of conducting experiments in insect-proof houses, but for experiments that can be completed in one year this is obviated by a new method of grafting by cores inserted from one tuber into another, planting being done in the open. Mosaic diseases are transmitted freely by using infected cores, but leaf roll does not appear to be transmittable unless the tubers are kept in the cold after grafting. This affords a useful means of separating mosaic from leaf roll infection by keeping the grafted tubers at about 20° C. before planting. If leaf roll infection is desired, cleft grafting on the sprouts is a very useful method of obtaining tuber infection. Cleft grafts are also reliable for infecting stalks and foliage, all diseases and combinations being equally transmitted, except occasionally streak, the latter, however, being readily transmitted by leaf mutilation. The rate of spread of virus in the potato plant has been studied by infecting single-stemmed plants at the top, and then removing the lateral shoots at intervals and growing them as cuttings, or by similarly removing tubers. In such plants the virus spreads to all parts of the stem and tubers after an interval of more than 8 to 10 days and less than 14 to 15 days. Further work deals with the isolation of streak, which causes much trouble in endeavouring to isolate other diseases, as it is frequently present in certain varieties of potatoes in which it does little or no harm and where its presence would never be suspected.

PLANT CUTICLES IN COAL.—Ordinary domestic experience convinces many of us that there are wide differences in coals. When it is considered what extensive vegetable remains must be embodied in the coal and what a varied panorama living vegetation provides, the fact seems less surprising if none the less annoying on occasion. Obviously not only the method of preservation, but also the nature of the original vegetation concerned must affect the quality of the coal, and from this point of view attention is being directed, under the ægis of the Safety in Mines Research Board, to the identification of characteristic vegetable debris, with the view of seeing whether any special properties, such as inflammability, show correlation with particular vegetable components. As Paper No. 17 of the Research Board (London: H.M. Stationery Office, 1926; 1*s.* net), V. H. Legg and R. V. Wheeler publish an account of their study of the chemistry of the cuticle of a living plant, *Agave americana*, and of the well-known paper coal from the Moscow basin, which consists almost entirely of compressed plant cuticles. They find this paper coal to be only very slightly attacked by alkalis. The authors state that they are now engaged in the separation of cuticles from bituminous coal by a method which leaves them unaltered in composition, with a view to their further chemical study. It must not be forgotten, however, that there are other fat impregnated layers, at least in living plants and peat deposits, which are likely to be as well preserved in coal as cuticles, and it is not clear that some of the excellent photomicrographs in Plate IV., described as of cuticles from bituminous coals, necessarily represent cuticles at all.

New Mexican Land Shells.—There seems to be always something new from Mexico in the way of land shells. Two more papers have lately appeared. Dr. P. Bartsch describes (*Proc. U.S. Nat. Mus.*, 77, art. 22) three new species of Holospira. Dr. Pilsbry and Prof. Cockerell (*Proc. Acad. Nat. Sci. Philad.*, 77) deal with a series of shells belonging to several genera including two new species of the carnivorous Glandina, bringing the total number of species of that genus known from north-western Mexico up to ten. They further describe a very handsome little helicoid, *Polygyra nayarita*, n. sp., from the State of Jalisco, Central Mexico.

Paragenesis of Pegmatites.—An important study of the minerals and their sequence in certain of the granitic pegmatites of Maine has been carried out by K. L. Landes, and the results are published in *The American Mineralogist*, vol. 10, 1925, pp. 355-411. The original pegmatite magma crystallised after the manner of a granite, accessories including tourmaline and beryl being followed in turn by microcline and quartz. Mineralisation then continued through the agency of ascending solutions which were also responsible for the development of pockets and cavities. A high-temperature hydrothermal phase came first and introduced minerals such as quartz, cleavelandite (albite), and various lithium-bearing species. Then followed an intermediate phase in which many rare lithium-manganese phosphates were deposited. The third and final phase is represented typically by quartz, cookeite (a lepidolite-like mineral), and purple apatite. Weathering by groundwaters was responsible for the last crop of minerals produced, the chief alterations being to clay minerals and manganese hydroxides. Many of the minerals, including some remarkable quartz pseudomorphs, are described in detail with analyses.

The Geology of South Africa.—The Geological Survey of the Union of South Africa has just issued a geological map of the Union on the scale of one to a million. The map is a revision of one that was compiled for and exhibited at Wembley. It now appears in four unmounted sheets, each 38 in. by 28 in. (Price 25*s.*) The colour scheme has been well chosen, and the printing and registration carefully executed. In all, 29 different formations are distinguished, and nowhere is there any source of confusion either in geology or topography. An explanation of the map (sold separately at 6*d.*) by the Director, Dr. A. W. Rogers, provides a valuable summary of the geological structure of the Union. An account of the physical features is followed by a description of the geological history and the outstanding structural features, and the pamphlet concludes with a table of formations, igneous intrusions, and earth-movements. The chief differences from former interpretations are (*a*) the removal of the Vredefort granite from the end of the Witwatersrand system, (*b*) the transferring of the former Lower Waterberg to the Upper Transvaal, (*c*) the assignment of the Bushveld complex to the Upper Transvaal, and (*d*) the inclusion of the Pilandsberg alkaline rocks with the Cape System at its base. The Swaziland system remains, as formerly, a convenient class into which all the older rocks are placed pending more satisfactory evidence of their ages. There is still no means of deciding whether the Transvaal system is Palæozoic or pre-Cambrian. This is a case where a determination of the age of the younger granites or of the Bushveld complex by radioactive methods would be of the utmost importance. At the moment one can only direct attention to the lead-ratios of the Katanga (probably Ordovician) and Morogoro (probably Late pre-Cambrian) uraninites. These suggest that the equivalents of the Transvaal and Waterberg systems are respectively of pre-Cambrian and early Palæozoic dates.

Rainfall of the Dutch East Indies.—The Royal Magnetical and Meteorological Observatory of Batavia has published volume 2 of a monograph on the rainfall of Java and Madura based on the observations of several hundred rainfall stations during the period 1879–1922. The atlas consists of fifteen beautifully printed maps on a scale of 1 to 1,000,000. Relief of the highest ground is shown by hill-shading. The first map shows the location of the stations, while the others give the mean annual and the monthly rainfall. Volume 1 of the monograph is to contain the tables and volume 3 the text. The text is in both Dutch and English.

Squalene.—An account of further research on the unsaturated hydrocarbon squalene, occurring in large amounts in certain shark-liver oils, appears in volume 1 of the *Scientific Papers of the Institute of Physical and Chemical Research, Tokyo*. Decomposition of the hexa-ozonide, together with other facts, show that squalene is a higher aliphatic terpene.

Inversion of Cane-Sugar.—The kinetics of the inversion of cane-sugar in acid solution have been reinvestigated by S. W. Pennycuick, of the University of Adelaide, whose results are given in the January number of the *Journal of the American Chemical Society*. In the presence of a large excess of water the reaction

$$C_{12}H_{22}O_{11} + H_2O = C_6H_{12}O_6 + C_6H_{12}O_6,$$

first investigated from this point of view by Wilhelmy in 1850, is usually assumed to be unimolecular, since the active mass of the water remains practically constant. According to the investigations of Worley in 1911 the unimolecular law is not followed, and Armstrong and Caldwell in 1905 asserted that, with weak acids, the earlier stages are represented by a linear and not a logarithmic concentration-time formula. Other observers state that the unimolecular law holds with weak acids but not with strong acids, whilst a number of investigators claim that the inversion process follows the unimolecular law within the limits of experimental error. The principal advance claimed in the above investigation is the elaboration of three methods by means of which the rotation at zero time may be directly determined. In this way it was found that the velocity constant k increases slightly and steadily during the inversion, the maximum increase not exceeding 5 per cent. The very constant results of other workers are probably vitiated by errors which are discussed in detail. The hydrogen ion activity also shows an increase, as measured by the hydrogen electrode, of from 1 to 3 per cent. during inversion, according to the strength of the acid used. The use of the bimolecular equation: Velocity $= k$(sucrose)(water) is shown to be unsound, and the inversion is best represented by the equation: Velocity $= k$(sucrose molecules per molecule of water)(H ion activity).

Archæology and Natural History in Lithuania.[1]

PREHISTORIC FLINT IMPLEMENTS.

AMONG the many remarkable achievements of archæological research during the last few years, not the least noteworthy has been the piecing together of the evidence for bridging the gap which, it was once almost an article of faith to hold, lay between the palæolithic and neolithic periods of the stone age. Dr. F. Birkner has recently added to the record of sites in eastern central Europe from which evidence has been obtained bearing upon this still obscure question. During the War a collection of stone implements was made by Dr. E. Stechow while on a zoological expedition in Lithuania. The implements were surface finds and came from Zubrovo, 55 km. north-east of Grodno on the banks of the Kostra, an affluent of the Niemen, from the shores of Lakes Bersztу, Oziery (Jeziory), and Nowaja Ruda. According to the description furnished by Dr. Stechow, the sites on which they were found agree in being strips of dry open land in the neighbourhood of marshy ground running along streams or on lake shores. Sometimes they are backed by wooded or forest land. Prof. Birkner compares a number of stone age sites in Lithuania recorded by Wandalin Szukiewicz from the banks of the rivers Mereczanka and Gruda and the Stegela, Ula, Duba, and Pielasa lakes.

The implements found by Dr. Stechow included knives of various forms, points of various types, arrowheads with concave bases, implements of geometrical form, triangular and trapezoidal, various forms of scrapers, gravers, axes, some of the latter of characteristic Scandinavian type. He refers to similar types recorded by Szukiewicz, and in both cases compares them with finds in Bavaria made during the last ten years in the neighbourhood of Lichtenfels. At Schönsreuth in particular a large number of scrapers and geometrical implements of Tardenois type was found, also at Ansbach and at Neumarkt. It is evident that a large proportion of the implements are of a character typically Tardenoisian. Dr. Birkner goes on to point out certain features which he maintains are common to the sites. They are for the most part located on open ground, sand, loam or gravel, sometimes, as in Lithuania, near marshy ground or on the shores of rivers and lakes. The implements themselves include gravers, which are to be referred to a palæolithic type, while they also include forms neolithic in character, as for example the axes and chisels. Taking all the circumstances into account, his conclusion is that they represent a distinct culture—*Oberfläschensteinzeit* as distinguished from *Wohngrubensteinzeit*. This culture belongs to a people living in dry open spaces, by fishing primarily and by hunting. The survival of palæolithic and relation to or occurrence of neolithic forms indicates a true transitional phase.

Taking these facts, and the distribution of the "*Oberflaschensteinzeit*" culture into account, Dr. Birkner takes a different view of the Tardenoisian and Azilian culture from that of Obermaier, who brings the Tardenois culture into relation with the Late-Capsian of Spain, from which centre it is distributed over middle and northern Europe, and groups together Late Capsian, Tardenois, and Azilian as Epipalæolithic. Dr Birkner, however, would regard the Tardenois culture of the "*Oberfläschensteinzeit*" as a true mesolithic culture developed by a hunting and fishing people, and distributed from eastern Europe as a centre to Syria, North Africa, and western Europe. Further, he holds that the progressive deterioration in the size of palæolithic implements, which reaches its extreme in the Tardenois types, is related to changes in the climate during the period.

While the evidence relating to this obscure period of prehistory is still far too scanty to justify dogmatic statement, an alternative explanation of the variety of forms to which Dr. Birkner refers may well be possible. The conditions in which these collections of varying types are found inevitably suggests the possibility of either a succession or an impact of cultures at different stages of development. Apart from this, the evidence of distribution is at present too slender to support his view; indeed it seems to point in the opposite direction.

BIRDS.

It is well known that during the War the advancement of science in many branches was not left out of sight, even close to the front. British and German men of science and collectors at least have done work on the eastern and western fronts in Europe, Mesopotamia, East Africa, and elsewhere. In Germany specialists were appointed and worked under the protection of and assisted by the military authorities in several places. Ornithologists are familiar with the "Avifauna Macedonica" by Dr. Stresemann, based on a collection of 3258 bird-skins made by the "Macedonian Scientific Commission," which appeared in 1920. The work before us gives the ornithological results of Dr. E. Stechow's explorations in Eastern Lithuania, chiefly north-east of Grodno, now belonging to Poland.

These countries are of special zoogeographical interest, because in them is found the boundary for several species with eastern and western representatives, which actually meet in Lithuania, and in some instances interbreed. Unless such subspecies are separated by obstacles like sea, desert, or enormous mountain ranges, their boundaries are often not quite sharp, forms either frequently interbreeding where they meet, or overlapping. The collection of 703 skins, however, gave also opportunities to study individual, sexual, and seasonal differences, and time and manner of moult. The author has, with full regard to the literature on the subject by Russian, Baltic, and more recently by a number of German ornithologists, made excellent use of the material entrusted to him. Of the many more interesting details the following may be pointed out.

The west European carrion crow, *Corvus corone corone*, is entirely replaced by the hooded crow, which the author regards as a subspecies of the former, calling it *Corvus corone cornix*. The jackdaw agrees fully with the Swedish *Coloeus monedula monedula*, and the author seems to doubt that *C. monedula soemmeringii* is separable. Both species of tree creepers are found, *Certhia familiaris* common, *C. brachydactyla*, which finds in Lithuania its north-eastern limit, rare.

Pp 257-406+9 Tafeln.

(München: Verlag der Bayerischen Akademie der Wissenschaften.)

Of the nuthatch, two forms occur, called *Sitta europaea europaea* and *S. eur. homeyeri*. This led the author to review the European forms of Sitta in 26 pages, and to supply a large folding map, showing their distribution and representing nine forms in colour. He explains that the extremes are very different, and must be named *Sitta europaea europaea* (Sweden) and *S. europaea cisalpina* (Italy), the former being the whitest, the latter the most richly coloured one, and that *caesia* (western and central Europe generally) and *homeyeri* (East Prussia, Baltic States) might have names, but that the various forms completely merge into each other; therefore he rejects the use of the names *sordida*, *reichenowi*, and *stolcmani*, as given to changeable, insufficiently defined units. He thus does not differ much from the arrangement in the "Vogel der palaarktischen Fauna," vol. 1 (1905), except that there the Italian form was only indicated, but not supplied with a name; of the British form with its pallid underside and the Spanish-Moroccan one he had no specimens to examine, and therefore only alludes to the former without comment.

The Lithuanian long-tailed tit belongs to the northern subspecies with entirely white head, *Aegithalos caudatus caudatus*, while the British form has wide black lateral stripes, and in central Europe a form is widely spread with the head either pure white without or with lateral black stripes. Of the genus Regulus (Goldcrest) only *R. regulus* is found, as in England, while in central Europe two species, *R. regulus* and *R. ignicapillus*, occur side by side, the latter becoming dominant in southern Europe, and being the only one inhabiting the forests of north-west Africa (Morocco, Algeria, and Tunisia). Woodpeckers are very well represented; besides the three British species (all in different subspecies), the black, the white-backed, the middle spotted, and the three-toed woodpecker inhabit the vast forests, the latter in a differentiated new subspecies, called *Picoides tridactylus stechowi*.

Where different geographical forms are separable, the northern one is in nearly all cases the one found in Lithuania. Exceptions are the bluethroat (*Cyanosylvia svecica cyanecula*) and the yellow wagtail (*Motacilla flava flava*), which are represented by the central European subspecies, while of Sitta the northern and central European forms meet, Picoides being intermediate between the northern and central European (mountain) forms, and the crested lark (*Galerida cristata*), and the buzzard (*Buteo buteo intermedius*) showing eastern influence.

Insects.

Four articles in the publications under notice are devoted to the natural history of Lithuania and neighbouring provinces. The first article (pp. 259-277) is by Dr. P. Sack, of Frankfurt a. M., and contains an enumeration of Diptera found in the "Urwald von Bialowies." In so far as certain families are concerned, the list is evidently far from complete, and the Brachycera and Cyclorrhapha appear to have been better worked than the Nematocera. The region is apparently rich in Syrphidæ and the larger Asilidæ, no less than seven species of Laphria, for example, being recorded.

Dr. H. Bischoff, of Berlin, gives a general list of the Lithuanian Hymenoptera, including the aculeates, ichneumons and saw-flies. This contribution appears to be remarkably complete, and it includes useful data respecting localities and times of occurrence. Of the Aculeata it is a matter of interest to British entomologists to note that the genus Bombus is represented by twenty species and numerous varieties, while Psithyrus only comprises the same six species that occur in Britain. There are seven species of Vespa, two of which, *media* and *saxonica*, do not occur in Britain. The Chrysididæ are represented by seven genera and eighteen species. The region appears to be rather poor in ants, only twelve species being recorded. There is a long and valuable list of Ichneumonidæ and the Tenthredinoidea are tolerably well represented. The Trichoptera and Ephemeroptera of the Bialowieser Wald (pp. 339-342) are listed by the well-known authority, Dr. G. Ulmer of Hamburg; in the first-mentioned order forty-three species are enumerated, but only five species of Ephemeroptera are recorded.

The fourth article (pp. 343-406) is by Dr. H. Klose, of Berlin, who gives a very full illustrated account of the history and practice of bee-rearing in the forest regions. Of special interest are the curious vertical log-hives used in that part of the world. Some of the older forms of these are carved with bizarre human effigies and several are figured from the "Brandenberg Beweherte Bienen-Kunst," dated 1696.

Annual Meeting of the Association of Technical Institutions.

THE annual general meeting of the Association of Technical Institutions was held in Regent Street Polytechnic on March 5 and 6. The new president (the Marquis of Londonderry) was unable to be present, and his presidential address was read by Lord Emmott, who prefaced his reading with a reference to the unofficial Committee which is at present inquiring into the relationship of technical education to other forms of education and to industry.

That the time is ripe for such an inquiry became evident during the Conference. Three of the papers submitted dealt with the education of employees in distributive trades—a matter which has hitherto received little attention. Prof. Knox's paper on "Recent Developments in the Teaching of Mining in Technical Colleges" was particularly noteworthy in view of recent suggestions that the mines of Great Britain are inefficiently equipped and managed. His description of the general manager (whose staff organisation has three main divisions: colliery engineering, colliery managing, and chemical engineering) is illuminating and deserves reproduction:

"He is by innumerable Acts of Parliament held legally responsible for the safety of all workmen in and about the mines. Besides having to supervise all the work of . . . engineering departments he must be fairly expert in Geology and Surveying . . . He must have an extensive knowledge of the Laws relating to Coal Mines, Use of Explosives, Use of Electricity in Mines, Workmen's Insurance and Compensation . . . the Law relating to Leases, Surface Supports, Trespass, Leasehold, and Copyhold, Railways, Local and Imperial Taxation, etc. Last, but most important of all . . . he requires to have a knowledge of psychology and be imbued with a broad understanding in the handling of workmen."

Lord Londonderry's theme included the twin problems of the increase in the numbers entering the 'black-coated' professions and the serious lack of skilled manual workers (which will be felt most keenly when industry revives). In spite of the development of scientific appliances and automatic machinery, he insisted upon the continued necessity for good craftsmanship, and submitted that preference is being given to 'black-coated' occupations because of causes not often considered. In the past we have allowed the manual worker to become skilled at the expense of his intellectual equipment: his formal education usually ceases after the elementary school—a matter which needs attention if there is ever to be a redress of the social balance to the advantage of the craftsman as opposed to the clerk. During recent years, too, there has been the factor of the enhanced cost of living: boys must earn quickly, and 'blind-alley' jobs have been accepted eagerly. Further, there can be no doubt that, not only does unemployment fall most heavily on the skilled worker during trade depression, but wages, too, in those times, fall below those for unskilled work. What incentive is there for parents to send a boy to a long apprenticeship if, at the end, he may receive 10*s.* per week less than an unskilled man? The obsolete apprenticeship system is a final point requiring reconsideration: among the many things the War taught us is the fact that a long apprenticeship is not always necessary for the production of skilled workers.

The most animated discussion of the Conference, however, centred round the question of 'Adult Education.' A Board of Education Circular (1355) appears to encourage local education authorities to organise and control 'adult education,' although intimate administration might be delegated to voluntary organisations acting as advisory committees or managing bodies. Prominent among such organisations is the Workers' Educational Association, but opinion concerning it appears to have been divided because it is alleged to have ceased to be an entirely independent organisation since it became one of the contributory bodies to a new scheme with the Trades Union Congress, and must therefore tend to be governed by the latter in its educational policy.

As part of the Conference, a paper on "The Place of the Local College (Technical Institution) in Adult Education" was read by Prof. Peers, and, in the discussion, opinion was divided as to whether local education authorities should, or should not, accept financial responsibility for this type of education. The whole matter is to be discussed further, but it is to be regretted that no one attempted to define 'adult education.' Education has suffered considerably from the tendency to divide it into watertight compartments. Already we have elementary, secondary, technical, and university education. Now another term is used to describe something which is looked upon as another compartment. No wonder there is confusion of objects and aims! A body of students (age 20 years plus) under a voluntary organisation studies psychology; that is 'adult education.' Students of the same age study engineering or commerce (in their broadest implications) in a technical institution: this type of education appears to be regarded as outside the field of adult education.

An ancient error still persists. Technical education is regarded as synonymous with vocational instruction. What are the facts? In most technical institutions the course subjects are so presented that they become an education liberal in the fullest sense. Again, in such schools there is always a large percentage of students taking subjects which are thoroughly non-vocational. These facts do not appear to be well known. The inquiry referred to by Lord Emmott is therefore timely.

The Fate of the Hexosephosphoric Acid Esters in the Mammalian Organism.

THE importance of compounds of hexose and phosphoric acid, both in the intermediary metabolism of carbohydrates and in the process of ossification, is now well established. One need only mention the origin of the lactic acid of striated muscle from a hexosediphosphate, the connexion between inorganic phosphorus and glucose in the mechanism of the action of insulin, the occurrence of hexosephosphates in the fermentation of yeast, and the hydrolysis of one of these esters present in the blood by means of extracts of bone. But our knowledge of their physiology is still very incomplete, so that interest is attached to any work which helps to fill the gaps O. Fürth and J. Marian (*Akad. Wissensch. Wien*, 1925, No. 18, p. 175) have attempted to follow the fate of the hexosediphosphoric acids in the mammalian organism, by injecting a pure neutral or acid sodium salt subcutaneously into dogs; this route was chosen in preference to feeding by mouth in order to avoid any bacterial decomposition in the intestine. It was found that the diphosphate was broken down; part of the phosphorus appeared in the urine as inorganic phosphate, but about half was retained in the body, together with all the hexose. The authors suggest that the portion retained was utilised by muscle in the formation of lactacidogen. No effects were produced on the general metabolism even by doses so large as 40 gm. per kilo. body weight. It is of interest to note that some preliminary chemical experiments have led the authors to suggest that the molecules of these compounds may possess a cyclic structure.

Fürth and Marian have shown that a hexosediphosphate can be utilised by the body after parenteral administration. H. D. Kay in some recent work (*Biochem. Journ.*, 1925, vol. 19, p. 433) has brought forward some evidence as to the tissues in which this destruction occurs. In an investigation into the phosphorus compounds of milk, he has found at least two organic acid-soluble phosphorus compounds in cow's, goat's, and human milk, one of which is readily hydrolysable by tissue extracts whilst the other is more stable. The fact that muscle extract does not hydrolyse the compounds at all readily suggests that they are not of the yeast hexosediphosphate type, although preliminary experiments indicate that the one, which is attacked by bone enzyme, is probably a hexosephosphoric acid ester. Of more interest in connexion with Fürth and Marian's work is the finding that the compounds present in milk are not attacked by saliva, gastric or pancreatic juice, but are broken down by the intestinal juice. On the other hand, most of the tissue extracts examined were active in this respect, including both extracts of gastric mucosa and pancreas, although the external secretions of these latter were inactive

It appears, therefore, that hexosephosphates are hydrolysed in the gut before absorption, but the general presence of hydrolytic enzymes in the tissues implies that under suitable conditions the latter will be able to synthesise these compounds, as is also suggested by the fact that the esters occur in the circulating blood. Kay finds that phosphorus is present in milk in no fewer than eight different forms, including free phosphate, caseinogen, phosphatides and acid-soluble esters, and suggests that this abundance is to ensure adequate absorption of this element. The compounds will be hydrolysed at different levels in the gut, and it is thus possible that the concentration of PO_4''' ions will be kept so low that the solubility product of calcium phosphate is not exceeded, thus obviating the precipitation of this insoluble salt in the alkaline or neutral contents of the intestine, with the resultant loss of both calcium and phosphorus in the fæces.

University and Educational Intelligence.

ABERDEEN.—Mr G Leslie Purser has been appointed lecturer in embryology. Mr. W. H. Bruford, reader in German, Mr. J. Macfarlane, reader in geography, and Dr. J P Kinloch, lecturer in public health, have been appointed members of the Senatus Academicus.

The University Court has resolved to institute a post-graduate course of study in the faculty of medicine, during the ensuing summer term, for the benefit of practitioners in the north-east of Scotland.

CAMBRIDGE —Mr. A Hutchinson has been reappointed demonstrator in mineralogy and assistant curator of the Mineralogical Museum.

L R Bishop, scholar of Trinity College, has been appointed to a Frank Smart studentship in botany. He was placed in Class I. in the Natural Sciences Tripos in 1925, and is engaged in research on respiration in plants.

Rayleigh prizes have been awarded to R C. Cooper, of Trinity College, and H Horrocks, of St. Catherine's College, for essays on "Some Inequalities applicable to the Theory of Functions" and "The Effect of Wind on Tides and Currents and the Decay of Waves in a Circular Basin" respectively

Smith's prizes have been awarded to G. S. Mahajani, of St. John's College, who wrote on the theory of ferromagnetic crystals, and Ll. H. Thomas, of Trinity College, whose essay dealt with Kronecker's theorem in relation to adiabatic invariants.

The University Appointments Board has presented the annual report reviewing the work during the past year of the Board and the present position of the labour market as it affects students who have finished their university courses. It is stated that there are many opportunities available for men with a knowledge of both chemistry and engineering; another point of importance is that there is a lack of candidates for good appointments on the educational side in the Dominions.

LONDON.—The title of professor of physiology in the University has been conferred on Dr. J. S. Edkins, in respect of the post held by him at Bedford College. During the War, Prof. Edkins was a member of the Physiology Committee of the Royal Society and of the Grain-Pest Committee, and he also acted as secretary of the Chemical Warfare Medical Committee (a joint committee of the War Office and Medical Research Council). Since October 1911 he has published a text-book on practical physiology (with Pembrey, Beddard, L. Hill, and McLeod) and papers on the physiological and histological effects of poisonous gases and vapours, on the effect of various gaseous reagents upon the flour moth (*Ephestia Kuhniella*) and other pests found in flour, and more recently on parasitic organisms in carnivores and on an organism normal to the human stomach.

OXFORD.—On March 9 the second annual report of the Committee of Management of the Lewis Evans Collection of Scientific Instruments was presented to Convocation. The report deals, in the first place, with the public opening of the collection on May 5, 1925, and then proceeds to record the work done on the structure of the Old Ashmolean Museum, which has resulted in the restoration of one of the features originally provided by Wren. The complete text of the mural inscription over the old Library door has now been recovered, and its restoration has been thereby rendered possible. A list is given of accessions during the past year, many of these are of great interest. They include an early example of a Sprengel mercury pump, a seventeenth-century pharmacy jar for the reconstruction of one of Mayow's experiments on respiration, and a copy of Lieut.-Col F. Pepys-Cockerell's well-known portrait of Samuel Pepys, F.R.S. A beginning has been made with the construction of models of obsolete instruments, notably the 'perspectograph' and bowl level designed by Wren for the rebuilding of London after the Great Fire. Prof. Jenkin has made a special study of the astrolabes in the collection, and has published an explanatory book. Many collections have been deposited on loan, among the contributors being New College, St. John's College, and the Curator of the Daubeny Laboratory at Magdalen College. The Library has been enriched by the accession of works by Elias Ashmole, given by his representative, Mr. Bernard Ashmole An account of the whole collection has been published by the Clarendon Press, under the title of "Historic Instruments for the Advancement of Science." At the conclusion of the report, the energetic Curator, Mr. R. T. Gunther, fellow of Magdalen College, directs attention to the need for service rooms and accommodation for office work in the Ashmolean Building itself, the deficiency being at present supplied by the provision of part use of the Curator's private study at Folly Bridge.

SHEFFIELD —The Council of the University has decided to confer the title of honorary professor of mining on Mr. Douglas Hay, formerly professor of mining.

The following appointments have been made: Dr. D. C Harrison to a lectureship in pharmacology; Mr H. Blacow Yates to a part-time demonstratorship in anatomy; Mr. R. A. Mott to the post of research assistant in fuel.

THE doctorates conferred in the sciences by American universities have increased in number sixfold during the past twenty-five years, the number conferred in 1900 and 1925 being 102 and 621 respectively The Research Information Service of the National Research Council has compiled annually since 1919–20 a classified list of the theses of the recipients of these degrees and a statistical analysis by university and by subject is published in *Science* of December 25, 1925, with an announcement that statistics regarding the doctorates in chemistry and a list of dissertations covering the period 1922–23 to 1924–25 will appear in the *Journal of Chemical Education*. The list of the theses is on file in the Research Information Service, and information regarding them will be furnished on request. Of the 621 doctorates conferred in the sciences in 1925, no less than 244 are classified under the head of chemistry. Zoology and botany come next with 71 and 65 respectively. These three with physics (56) and psychology (51) include more than three-fourths of the total number of doctorates, the remainder being distributed among geology (25), mathematics (22), bacteriology (20), physiology (17), agriculture (13), geography (13), and eight other sciences (24). The number of doctorates conferred in mathematics has decreased noticeably since the War years, whereas almost every other subject shows an increase. Of the seven hundred and odd degree-conferring institutions in the United States, only forty-one conferred the doctorate in science in 1925, and of these, Wisconsin, Chicago, and Columbia head the list with 64, 59, and 51 respectively. Harvard conferred only 25.

Contemporary Birthdays.

March 21, 1861. Sir George Hadcock, K.B.E., F.R.S.
March 21, 1873. Dr. Andrew Balfour.
March 21, 1865. Right Hon. Herbert A. L. Fisher, F.R.S.
March 22, 1868. Dr. Robert A. Millikan.
March 25, 1863. Dr. Simon Flexner, For.Mem.R.S.

Sir GEORGE HADCOCK, formerly an officer in the Royal Artillery, is managing director of Sir W. G. Armstrong, Whitworth and Co., Ltd. He is an associate member of the Ordnance Committee. Sir George has written much on modern artillery developments. He is Hon.D.Sc. (Durham).

Dr. ANDREW BALFOUR was born at Edinburgh and educated at George Watson's College, and at the Universities of Edinburgh, Cambridge, and Strasbourg. He was Director of the Wellcome Tropical Research Laboratories, Khartoum, 1902–13, and for most of that period Medical Officer of Health, Khartoum. In 1918 he was president of the Egyptian Public Health Commission. Dr. Balfour is Director of the London School of Hygiene and Tropical Medicine.

Mr. FISHER is a Londoner, and was educated at Winchester, New College, Oxford, and at Paris and Göttingen. He was Vice-Chancellor of the University of Sheffield, 1912–16; then he became President of the Board of Education, holding office until 1922. In 1925 he was designated Warden of New College, Oxford. He is also a trustee of the British Museum. Mr. Fisher delivered the Lowell lectures at Boston, Mass., in 1909 and 1924. He was a member of the Royal Commission on the Public Services of India, 1912–15.

Dr. MILLIKAN, Director of the Norman Bridge Laboratory of Physics, Pasadena, California, was born at Morrison, Illinois, U.S.A. He graduated at Oberlin College, Ohio, and for two years afterwards taught elementary physics there; later on he occupied the chair of physics in the University of Chicago. He was Nobel laureate in 1923. Dr. Millikan's researches in the fields of electricity, optics, and molecular physics have been of outstanding importance. Most notable was the measurement of the charge of the electron. It was recorded that "this work furnishes the most direct and complete demonstration which has yet been found of the atomic structure of electricity." Recently he has announced the discovery of high-frequency radiation of cosmic origin. Dr. Millikan was Hughes medallist of the Royal Society in 1923. He is the author of "Science and Life" (1923).

Dr. SIMON FLEXNER was born at Louisville, Kentucky, and took his doctorate in medicine at the university of that city in 1889. He studied also at Johns Hopkins University, and at the Universities of Berlin, Prague, Strasbourg, and Paris. At the first-named he was professor of pathological anatomy, 1889–99, afterwards occupying a similar chair at the University of Pennsylvania until 1903, leaving to become Director of the Laboratories of the Rockefeller Institute for Medical Research, New York. He is an Officer of the Legion of Honour of France, Hon.LL.D., Cambridge, and D.Sc., Harvard, Yale, and Princeton Universities. Dr. Flexner is the author of many papers and monographs relating to bacterial and pathological subjects, including "The Bio-chemical Constitution of Snake Venoms"; "Epidemic Cerebrospinal Meningitis and its Serum Treatment"; "Experimental Epidemiology."

Societies and Academies.

LONDON.

Royal Society, March 11.—**J. A. Campbell**: The effects of ultra-violet radiation upon the metabolism of healthy subjects. Radiation by total rays (223 $\mu\mu$–770 $\mu\mu$) from the mercury-vapour lamp, or by the group of rays through blue uviol glass (290 $\mu\mu$–436 $\mu\mu$), or by the visible rays from either of these sources (400 $\mu\mu$–770 $\mu\mu$ and 400 $\mu\mu$–436 $\mu\mu$ respectively) has no effect upon the metabolism of healthy men, mice, or rats. When mice lie together in groups there is apparently a decrease of carbon dioxide output due to reduction of surface area. A simple method of estimation of carbon dioxide output and oxygen intake in small animals is described.—**E. Ponder**: A study of certain forms of inhibition and acceleration of hæmolysis. Four types are recognised: (1) the inhibition produced by plasma and serum, described by expressions which suggest an interaction between the plasma or serum and the lysis not unlike those which occur in adsorption processes; (2) the inhibition produced by certain bases, sugars, and neutral salts, which are described by linear expressions; (3) the acceleration produced by acids and by certain salts, also described by linear expressions; and (4) the acceleration produced by plasma or serum when added to a hæmolytic system in which the lysis is one of the bile salts or soaps. Types (2) and (3) are the most generally met with, and the expressions necessary for their description are given, the object of the study being to investigate the kinetics of such hæmolytic systems. In the case of substances the reaction of which is not neutral, the effect is not wholly dependent on the *p*H.—**S. B. Schryver** and **H. W. Buston**: The isolation of some undescribed products of hydrolysis of proteins. From the hydrolysis products of one of the oat proteins, two hitherto undescribed amino-acids were isolated by the authors' 'carbamate method' and were found in the non-basic fraction of the soluble barium carbamates. These latter can, by means of the zinc salts, be separated into three main fractions, one of which contained two amino-acids. These were separated by taking advantage of the fact that one gave a copper salt insoluble in methyl alcohol and the other a copper salt soluble in this solvent. The former has a formula corresponding with hydroxyaminobutyric acid, $C_4H_9O_3N$, and gave a dibenzoyl compound, m.p. 112°, and a phenylisocyanate compound, m.p. 143°. The other amino-acid has a formula corresponding with hydroxyvaline, $C_5H_{11}O_3N$, and gave a dibenzoyl compound, m.p. 117°, and a phenylisocyanate compound, m.p. 145°. There is evidence of the presence of other undescribed substances.—**A. W. Greenwood** and **F. A. E. Crew**: Studies on the relation of gonadic structure to plumage characterisation in the domestic fowl. Into a brown leghorn hen, ovariotomised when four days old, the testes of a brother were implanted. The bird first assumed the plumage characterisation of the cock, but after a general moult its plumage became as that of a hen. Post-mortem examination revealed a small fragment of degenerate ovarian tissue left behind at the time of operation, an active right gonad of testicular structure, and abundant testicular tissue which had developed from the grafts. Ovarian and testicular tissues in respect of their own individuation seem to exert demands upon the general economy of the same kind but different in degree; the functioning of an ovary is physiologically more expensive, but it is possible to augment the demands of the testes until they become equivalent to the ovary. This hen became cocky-feathered because in her body at this time there was active testicular tissue; later she became henny-feathered because the amount of testicular tissue had become greatly increased and had exerted demands upon the body equivalent to those of an active ovary.—E. P. **Cathcart** and W. A. **Burnett**: The influence of muscle work on metabolism in varying conditions of diet. A long series of muscle-work experiments were carried out on a human subject living on different types of diet: (1), low nitrogen, meat-free; (2), high nitrogen, meat-free; (3), as in (1), but meat extractives added; and (4), a meat-containing diet. The nitrogen exchange and the respiratory exchange were both studied. A definite rise in both the output of nitrogen and sulphur resulted from muscle work. Only a slight disturbance in the distribution of the nitrogen-containing constituents in the urine was noted. The consumption of oxygen seemed to be dependent to some extent on the nature of the food consumed.—E. **Fischer**: The heat liberated by the beating heart.

Royal Meteorological Society, February 17.—T. H. **Somervell**: On temperature at high altitudes: meteorological observations of the Mount Everest Expedition, 1924. The performance of any little extra work, such as even the recording of a temperature, is very irksome at high altitudes. Temperatures were usually recorded at 8.30h., 12h., and 16h. each day, and readings were taken from a minimum thermometer freely exposed to the sky about one foot above the ground. The lowest temperature recorded from this freely exposed thermometer was at Camp 3 (21,000 ft.), the reading being −24° F. Only a few observations were taken at Camp 4 (23,000 ft.) towards the close of the expedition.—F. J. W. **Whipple**: The significance of the observations (above), and particularly the lapse rate of temperature with respect to height.—Vaughan **Cornish**: Observations of wind, wave, and swell on the North Atlantic Ocean. The speed of the waves measured directly by the time taken to run the length of the ship, and the period as measured by the intervals between their arrival, gives an observed speed in agreement with that calculated from the period by the usual mathematical formula. Using a new and speedy method for determining the period of waves at sea which permits the separation of the wave proper from the swell, it was found that when there was no crossing swell, the speed of the waves was so nearly equal to that of the wind that their crests were travelling in almost calm air. When there was a crossing swell, the wind was unable to produce waves travelling with nearly its own speed, the deficiency being increased when the crossing swell was not from a following but opposing direction. The height of the waves was also kept down by crossing swell; this leads to an underestimate of the force of the wind as entered in the ship's log. The direction of the wind is more reliably recorded by the general run of the waves.—L. G. **Garbett**: Admiral Sir Francis Beaufort and the Beaufort Scales of Wind and Weather.—Admiral Sir Francis Beaufort was for twenty-six years Hydrographer of the Navy. Extracts from Beaufort's private logs show the interest he took in the study of the weather. The Beaufort scales were devised in 1806 by Beaufort when in command of H.M.S. *Woolwich*, but were not introduced into the Navy until 1838, and then in a form somewhat modified from the original.—J. **Bartels**: On the determination of minute periodic variations. A method is described for obtaining the best possible values for amplitude and phase of a periodicity of given length, if the period is hidden by comparatively large irregular fluctuations. The scheme is applied to the determination of the lunar diurnal variation of atmospheric pressure in higher latitudes.

Linnean Society, February 18.—C. C. A. **Monro**: Polychæta of the *Alert* Expedition: families Hesionidæ and Nereidæ. This paper is the last of the series containing a systematic account of the Polychæta collected by H.M.S. *Alert* during her voyage in 1881–82. It is an account of the families Hesionidæ and Nereidæ and attempts to place the classification of the genus Hesione on a more satisfactory basis. All the examples are from the Indo-Pacific area.—J. **Ramsbottom**: "Fairy rings" in air-photographs.—F. O. **Bower**: A scheme of phyletic grouping of ferns. In "The Ferns," vol. 1., an analysis has been given of those criteria of comparison of the ferns which may be used with the view of their phyletic grouping. These have been arranged under twelve heads. An 'archetype' for the class would seem to be substantially similar to plants which were actually living in the Devonian period, namely the Psilophytales. It would consist of a simple upright shoot of radial symmetry, possibly rootless, dichotomising if it branched at all, and with the distinction between axis and leaf ill-defined. The whole plant would be relatively robust as regards cellular construction, and traversed by conducting strands with a solid xylem-core. The solitary sporangia would be relatively large and distal in position, with thick walls and a simple method of dehiscence, and each would contain numerous homosporous spores. Vol. 2 of "The Ferns," now passing through the press, is devoted to those ferns which both comparison and palæontology indicate as relatively primitive. They include all the eusporangiate ferns, together with certain families which have archaic features. The eusporangiate and leptosporangiate types, with intermediate types, are Simplices, and all date back to Mesozoic or even to Palæozoic time. Their existence makes it appear probable that in the course of descent a gradual transition took place from the eusporangiate to the leptosporangiate state. In vol. 3 of "The Ferns" an attempt will be made to trace the phyletic relationships between the various groups.

Faraday Society, February 22.—A. J. **Allmand** and R. H. D. **Barklie**: The influence of alternating currents in the electrolytic corrosion of iron. The corrosion of iron in alkaline solutions by direct current, alternating current, and by alternating current superposed on direct current has been investigated. The superposition of the two types of current causes relatively increased corrosion. A similar result has been found when using typical subsoil drainage liquid saturated with carbon dioxide. Experiments have also been carried out on the accelerating effects of added alkaline chloride on corrosion in alkaline solutions.—A. N. **Campbell**: The direct oxidation of manganous ion to permanganate. The conditions under which manganous ion can be anodically oxidised to permanganate have been studied, and the optimum conditions evaluated. Only permanganate is produced by this oxidation.—H. J. **Poole**: The elasticity of jellies of cellulose acetate in relation to their physical structure and chemical equilibria. The load-strain curve for cellulose acetate jellies bends continuously towards the load axis, suggesting a sponge-like or fibrillary structure of rigid material in the jelly. The elasticity in a solvent consisting of benzyl alcohol and water in constant ratio follows approximately the square of the concentration. Thus the material of the rigid phase exists as a result of a dynamic solvation equilibrium between the cellulose acetate and the solvent. Permanent deformation was not induced by heating and cooling temporarily deformed specimens, so the structure first formed on gelation is mainly of a permanent nature. Equilibrium in elastic properties was only reached after a considerable period following a change in temperature. The creep under stress was studied and a coefficient of inner resistance proposed. Values of this coefficient run parallel with the viscosity of the parent sols. Benzyl alcohol as a solvent is deficient in OH groups Partial replacement of benzyl alcohol by water resulted in a decrease in elasticity and an increase in solvation. On the other hand, partial replacement by xylene resulted in an increase in elasticity and a decrease in solvation.—**F. G. Tryhorn** and **W. F. Wyatt**: (1) The adsorption by a coconut charcoal of saturated vapours of some pure liquid. The adsorptive power at 20° C. of a purified coconut charcoal has been determined for fourteen liquids. The initial rate of adsorption, in accordance with the laws of diffusion, is proportional to the vapour pressure of the liquid, and inversely proportional to the square root of its molecular weight. For eleven of the liquids the velocity of adsorption is a discontinuous function of time. The discontinuities may correspond with the sudden formation of a liquid surface in the charcoal. (2) Stages in the adsorption by a coconut charcoal from vapour mixtures of alcohol and benzene and of acetone and benzene The adsorption curves consist of three parts. The first stage is adsorption of the two components in a constant ratio. When the density of the adsorbed vapour exceeds a certain value, condensation to a liquid occurs in the charcoal. This marks the second stage, which continues until the liquid phase is in equilibrium with the bulk liquid With the charcoal employed, this change occurred without further increase in the total number of moles adsorbed, and in every case involved displacement of alcohol or acetone by benzene. The difference between the compositions of the adsorbed liquid phase and of the bulk liquid is attributed to selective adsorption. The third stage of the adsorption process is one of isothermal distillation of the bulk liquid into the intergranular spaces of the charcoal, and is the result of the curvature of the liquid surfaces at the points of contact of the grains.—**I. R. McHaffie**. A device for circulating fluids under high pressure. This is essentially an electro-magnetically operated pump which by a suitable arrangement of valves produces a constant flow of gas in the desired direction. It has been used continuously for the circulation of air at pressures up to 100 atmospheres.

DUBLIN.

Royal Dublin Society, February 23.—**W. E. Adeney** and **Miss B. B. Dawson**: The estimation of organic matter in water by means of potassium bichromate and sulphuric acid. These reagents are used for the estimation of small quantities of oxidisable matter in water; the method is especially valuable for dealing with sewage liquors.—**T. G. Mason** and **C. J. Lewin**: On the rate of carbohydrate transport in the greater yam, *Dioscorea alata* Linn. Experiments carried out on a large scale in southern Nigeria proved that the average increase of tuber dry weight per stem amounted to 45 gm. a week during the period of maximum growth. Assuming the concentration of carbohydrates in the sieve tubes to be 25 per cent, this would represent a velocity of 88 cm. per hour. A movement at this rate through the sieve tubes being clearly impossible, it is concluded that, even if high concentrations are assumed, the phloem is incapable of transmitting the main flow of carbohydrate.—**J. Reilly**, **P. J. Drumm**, and **C. Boyle**: The production of lavender oil from Irish-grown plants. Preliminary experiments on the production of lavender oil from Irish-grown plants have yielded promising results. Further work on a larger scale is in progress. The possibility of the economic production of high-grade lavender oil in Ireland is considered.

EDINBURGH.

Royal Society, February 22.—**Rev. T Crouther Gordon**: The finding of the Galilee skull. An excavating expedition was organised in the spring of 1925 by the British School of Archæology in Jerusalem, to examine some caves in Wadi 'Amud in Galilee. In the largest cave there were 110 cm. of stratified deposits on the floor, and below this a petrified layer of prehistoric flints All the historic periods were represented by the 28 strata Beneath two large stones in the Palæolithic level the frontal bone of a human skull was found, along with the malar bone, and the right half of the sphenoid bone, completely petrified. The pronounced supra-orbital ridges mark it as distinctly Neanderthal in type, and the associated flints testify to the same culture. It is the first trace of the Mousterian type of man outside of Europe.

MANCHESTER.

Literary and Philosophical Society, February 23 — **T. A. Coward**: (1) The vertebrates of the Manchester district; a contribution to the regional survey. There are moorland, foothill, lowland, mossland, and urban faunas. The true moorland fauna has, perhaps, the most exclusive character; it is confined to the higher hills to the north and east of Manchester, typical grouse-moors with spongy mosses and rocky outcrops. The foothill and lowland faunas have much in common, though certain animals are typical of each. The foothills lie south and west of the moors; the lowlands, partly agricultural, partly suburban, extend farther to the south and west, and contain many parks, woodlands, and lakes or meres inhabited by animals which are mainly characteristic of these environments. The mosslands are, or were, in the river valleys, and are in a transition stage, drainage and cultivation and the growth of residential areas constantly altering the character of the fauna. The urban fauna is that which is restricted by the populated areas, and it too suffers change through increase in population, but is recovering some of its former character under the influence of municipal protection and the provision of open spaces and parks. (2) The vertebrates of the Shetland Isles. Certain of the characters of the fauna are due to latitude and isolation. Terrestrial mammals are few, and one at least, the wood-mouse, is an insular form, having much in common with the mouse of the Faeroes; other animals owe their status to introduction rather than survival. Although there is a large passage avifauna, resident birds are not numerous in species though abundant in individuals; most of them have a marine life. Two of the resident passerine birds are insular forms, and others are of a northern type. Cetaceans and pinnipedes are more numerous than in any other part of the British Islands The fish, except for migratory species like the herring, are of northern type. Thanks to protection, the birds are rapidly increasing in numbers, but other factors influence the spread and colonisation of the fulmar, gannet, and perhaps one or two other species.

PARIS.

Academy of Sciences, February 22.—**A. Lacroix**: A new eruption of the volcano of Reunion (December 30-31, 1925). This eruption took the same form as that of September 12, 1924, and the lava is flowing in the same direction.—M. Georges Perrier was elected a member of the section of geography and navigation in succession to the late L. Gentil.—B. **Hostinsky**: The transformation of differential expressions.—N. **Saltykow**: The general integral of characteristics.—Paul **Lévy**: A theory of growth.—N. **Boneff**: The origin of satellites.—Thadée **Pecsalski**: The crystallisation and sublimation of the metals. Continuing previous experiments on the cementation of metals by salts, experimental proof is given of the sublimation of metals in contact with their salts, the vapours of the metals arising from the reduction of the chlorides.—**Michel-Samson**: The change of the coefficient of expansion of substances in the amorphous state. Experiments on silicates, borates and phosphates described in an earlier communication have been extended to amorphous organic substances. From the experiments detailed it is concluded that all bodies in the amorphous state show a discontinuity in the coefficient of expansion for a viscosity of the order of 10^{14} poises. To this discontinuity there corresponds a change in all the physical properties. In the case of the silicates this anomaly has been attributed to a change in the allotropic state of the silica. It is, however, a general property of matter.—Jean A. **Athanasiu**: The use of mixtures of water and alcohol in the electrometric study of reactions by precipitation. An enumeration of the advantages presented by the use of aqueous alcohol (30 per cent.) in place of water in some electrometric estimations of cerium, barium, mercury and lead.—S. **Glixelli** and Mlle. **Deniszczukowna**: The preparation and properties of solutions of antimonic acid.—Albert **Portevin**: The fringes due to cold hardening or corrosion. An account of the superficial deformations of the crystalline grains produced by polishing and of the effects shown after etching.—André **Kling** and Daniel **Florentin**: The hydrogenation of organic substances at a high temperature and under high pressures in the presence of non-hydrogenating catalysts. It was to be supposed that the addition of catalysts would lower the temperature at which hydrogenation under pressure takes place, and this has been confirmed by experiment. The examples given include the production of cyclohexane and normal hexane from cyclohexanol in the presence of alumina, and of benzene, toluene, xylene, etc., from naphthalene in the presence of ferric or aluminium chloride.—**Pastureau** and **Bader**: The chlorhydrins of some unsaturated $\alpha\beta$-ketones.—Albert **Michel-Lévy**: Crushed zones and mylonites later than the Stephanian in the crystalline Maures massif.—P. **Corbin** and N. **Oulianoff**: The chain of the Aiguilles Rouges in the alpine orogenic movement.—Casimir **Rouppert**: Benzidine as a reagent in living plants. An account of results obtained by the culture of the bean in weak benzidine solutions.—O. **Munerati**: The possibility of determining the age of grains of wheat by the temperature of their germination. From a study of the manner in which the seeds germinate when exposed at temperatures varying from 32° C. to 6° C., the age of the seeds, if collected within three years, can be accurately judged. It follows from this that the optimum germination temperature of seeds, at least so far as concerns cereals, is a function of the age of the seed.—Mlle. Panca **Eftimiou**: Nuclear evolution in the Exoasceæ.—Davy de **Virville**: The action of the subterranean medium on the mosses.—L. **Lavauden**: The presence of a cypress in the mountains of Tassili des Azdjers (Central Sahara).—Jules **Amar**: Growth and alimentary interactions.—L. **Fournier** and A. **Schwartz**: The preventive action of bismuth in experimental syphilis of the rabbit.

Diary of Societies.

SATURDAY, March 20.

British Mycological Society (at Lister Institute), at 11 A.M.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (3).

Institute of British Foundrymen (Lancashire Branch, Junior Section) (at Manchester College of Technology), at 7.—A Hodgkinson: A General Talk on Foundry Work.

Hull Association of Engineers (at Hull Technical College), at 7.15.—W A. Jackson Machinery and Plant Maintenance in the Textile Trade.

Physiological Society (at University College).

MONDAY, March 22.

Royal College of Surgeons of England, at 5.—Mr. Shattock: Demonstration of Specimens of Surgical Affections of the Kidneys.

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—L. C Grant: Developments in High Power Fuses.

Royal Society of Medicine (Odontology Section), at 7.30—F N. Doubleday: Demonstration of Blood Films and Kiamographic Records of Hearts—At 8—F. N. Doubleday: Action of Local Anæsthetic Solutions on Living Cells

Aristotelian Society (at University of London Club), at 8—J Levine: Naturalism and Values.

Royal Society of Arts, at 8—W. F. Higgins: Thermometry (Cantor Lectures) (2)

Royal Geographical Society (at Æolian Hall), at 8.30

Medical Society of London, at 8.30—Prof Blair Bell. The Use of Lead in the Treatment of Malignant Disease.

TUESDAY, March 23.

Royal Dublin Society, at 4 15.—Prof. W. E. Adeney: On the Rate and Mechanism of the Aeration of Water under Open Air Conditions.—J. Bell: The Constitution of Dicyano Diamide with a Note on the Formation of a Mercury Derivative—Prof. J. Doyle and Miss P. Clinch: The Pentoran Theory of Cold Resistance applied to Conifers.

Royal College of Physicians of London, at 5.—Sir Thomas Horder, Bart Endocarditis (Lumleian Lectures) (1)

Royal Institution of Great Britain, at 5.15.—Prof. C. H. Desch: The Growth of Crystals (2).

Institution of Petroleum Technologists (at Royal Society of Arts) (Annual Meeting), at 5.30.—Sir Thomas H. Holland: Presidential Address.—Discussion on paper by Dr. Wade on The Search for Oil in Australia.

Zoological Society of London, at 5 30.—Secretary: Report on the Additions to the Society's Menagerie during the month of February 1926—J Omer-Cooper: A Revision of the Genus Periscyphis Gerst. (*Isopoda Terrestria*)—B. N. Schwanwitsch: On the Modes of Evolution of the Wing-pattern in Nymphalids and certain other Families of Rhopalocerous Lepidoptera.—R I Pocock: (a) The External Characters of the Jamaican Hutia (*Capromys brownii*); (b) The External Characters of the Flying Lemur (*Galeopterus temminckii*).

Manchester Literary and Philosophical Society, at 5.30.—Prof A Sommerfeld: The Periodic System, Chemical Bonds, and Crystal Structure.

Institute of Marine Engineers, at 6.30.—D. Brownlie: Super-Pressure Steam Generation.

Institution of Electrical Engineers (East Midland Sub-Centre) (at University College, Nottingham), at 6.45—C. C. Sutton and J. H. R. Nixon. Power Factor.

Institution of Automobile Engineers (at 83 Pall Mall), at 7.—Prof J. J. Guest: The Main Free Vibrations of an Autocar.

Society of Chemical Industry (Glasgow Section), at 7.—R. Maclaurin: Causes of Reactivity and Inactivity in Cokes

Institution of Electrical Engineers (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—J. W. J. Townley: The Operation of a Modern Power Station.

Royal Photographic Society, at 7—B Park: A Glimpse of Corsica l'île parfumée

Institution of Engineers and Shipbuilders in Scotland (at 39 Elmbank Crescent, Glasgow), at 7.30.

Institute of Chemistry (Edinburgh and East of Scotland Section) (and Society of Chemical Industry (Edinburgh and East of Scotland Section)) (at 36 York Place, Edinburgh), at 8.—Sir W. H. Perkin: The Early History of Ring Closure.

WEDNESDAY, March 24.

Society of Chemical Industry (Chemical Engineering Group) (at Chemical Society), at 3 and 6.—Symposium on Bearings and Lubricants:—R. Amberton: Roller Bearings.—R Allan: Ball and Roller Bearings. Characteristics affecting their Practical Application and Use—Dr. A. E. Dunstan and R W L. Clarke: The General Properties of Lubricating Oils and their Practical Application.—J H. Hackford. Some Characteristics of Lubricating Oils

Institute of Hygiene, at 3.30.—Lieut.-Col R. H Elliot. Eye Troubles of School Life.

Royal Society of Medicine (Comparative Medicine Section) (jointly with Electro-Therapeutics Section), at 5.—Dr. J. F. Halls Dally: Ultra-violet Radiation in Man.—E. Middleton Berry: The Therapeutic Effects of Ultra-violet Rays and High Frequency Currents in Animals—Prof Leonard Hill, Dr. Weinbein, Dr. H. Munro, H Stainton, and Dr. L. Dobson: Discussion on above.

Geological Society of London, at 5.30.—Sir T. W. Edgeworth David: The Physiography and Tectonic Structure of the Commonwealth of Australia (Lecture)

Radio Society of Great Britain (at Institution of Electrical Engineers), at 6—Prof. E. W Marchant. Fading (Lecture)

Royal Microscopical Society (Industrial Applications of the Microscope Section), at 7.30.—James Swift and Son, Ltd.: Exhibition of Prof. S J. Shand's Recording Micrometer and a Screw Measuring Microscope—R. and J. Beck, Ltd. Exhibition of (1) Proof Plates; (2) Lewbeck Micrometer; (3) Cobweb Micrometer; (4) Micrometer Eyepiece; and (5) Barnard's Interferometer Plates—At 8—W. H. Johnson: The Use of the Microscope as a Measuring Instrument.

THURSDAY, March 25.

Chemical Society (Annual General Meeting) (at Manchester University), at 4.—Dr. A. W. Crossley: Presidential Address

Royal Society, at 4 30—E B. Verney: The Secretion of Pituitrin in Mammals, as shown by Perfusion of the Isolated Kidney of the Dog.—H. W. Florey and H. M. Carleton: Rouget Cells and their Function.—*To be read in title only*—Seana King. Oogenesis in *Oniscus asellus*—R. M Sargent. The Relation between Oxygen Requirement and Speed in Running

Royal College of Physicians of London, at 5.—Sir Thomas Horder, Bart.: Endocarditis (Lumleian Lectures) (2)

Royal Institution of Great Britain, at 5 15—Prof. J. Holland Rose The Indecisiveness of Modern Warfare (2)

Royal Aeronautical Society (Students' Section), at 6.—S. S. Hall: Stalled Flying

British Astronomical Association (West of Scotland Branch) (at Royal Technical College, Glasgow), at 7 30.—Rev J. T. Bird: Austral Orientation, with Special Reference to the Calendar and to the Teaching of Geography.—Dr. G. D C Stokes: The Equation of Time.

Institute of Chemistry Students' Association (London), at 8—Debate.

Tuberculosis Society (jointly with Society of Superintendents of Tuberculosis Institutions) (at Cambridge)—Sir Humphry Rolleston, Sir St. Clair Thomson, Prof. E. Collis, Prof. L. Cummins, Dr. J. Crocket, and Dr G Marshall. Communications.—Demonstration by Dr H. De Carle Woodcock: Apparatus for Artificial Pneumothorax—Dr. C. Riviere, Dr. V Pearson, M Davies, and Dr. P. Morgan: Discussion on the foregoing.

FRIDAY, March 26.

Electrical Association for Women (at Holophane, Ltd., Elverton Street, S.W.), at 3.—Scientific Illumination.

Physical Society of London (at Imperial College of Science and Technology), at 5.—L Backhurst: Obliquity Corrections in Radium Estimation.—Dr A. Griffiths and P. C Vincent: The Viscosity of Water at Low Rates of Flow, Determined Comparatively by a Method of Thermal Convection.—Dr. E. H. Rayner. Demonstration of Some Simple Experiments with Thermionic Valves.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimens of Spina Bifida and Allied Conditions.

Institution of Municipal and County Engineers (Metropolitan District Meeting), at 6.30.—J. Garvie: The Life of Wood Paving as affected by Expansion.

Institution of Mechanical Engineers, at 7.—S. Hunter and others: Discussion on 'Perlit' Iron.

Royal Photographic Society, at 7.—J. MacSymon: A Criticism of the 1925 Competition Prints.

Royal Sanitary Institute (at Guildhall, Derby), at 7.—Dr. P. Turton, Dr. E. Milligan, and others. Discussion on Goitre.—C A Clews and others: Discussion on Some Aspects of the Housing Problem.

Manchester Association of Engineers (at Engineers' Club, Manchester), at 7.15.—P W Seemer: Hydro-electric Engineering

Junior Institution of Engineers, at 7.30.—A. B Miller: Metal Aeroplane Construction.

Royal Institution of Great Britain, at 9.—Sir Ernest Rutherford: The Radiation from Atomic Nuclei.

Society of Chemical Industry (Chemical Engineering Group).—Symposium on Bearings and Lubricants.

Manchester Literary and Philosophical Society.

Tuberculosis Society (jointly with Society of Superintendents of Tuberculosis Institutions) (at Cambridge) (Continuation.)

SATURDAY, March 27.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (4)

North of England Institute of Mining and Mechanical Engineers (at Neville Hall, Newcastle-upon-Tyne), at 3.—J. F. C. Friend: Winding Ropes.

Tuberculosis Society (jointly with Society of Superintendents of Tuberculosis Institutions) (at Cambridge). (Continuation.)

PUBLIC LECTURES.

SATURDAY, March 20.

Horniman Museum (Forest Hill), at 3.30.—C. Daryll Forde: Agriculture and the Origin of Civilisation.

MONDAY, March 22.

Maidstone.—Sir Wilfred Beveridge: Insects in Relation to Public Health (Chadwick Lecture).

THURSDAY, March 25.

Dyers' Hall (Dowgate Hill, E.C.), at 6.—Dr. H. Levinstein The Dyestuff Industry and the State.

SATURDAY, March 27.

Horniman Museum (Forest Hill), at 3.30.—Dr. H. S. Harrison: Early Man and his Wanderings.

CONGRESS.

April 2 to 23.

Jerusalem and Beirut, International Archæological Congress.

SATURDAY, MARCH 27, 1926.

The Electricity Supply Bill.

THE Electricity Supply Bill, the text of which has now been published, contains no surprises. The framers of the Bill have kept two eminently desirable objects in view, namely, the utilisation to the best advantage of the heat generated by the combustion of coal and the cheapening of the supply of electrical energy in Great Britain for lighting and power to the consumer. The project if carried out will increase the value of coal and will prevent its waste. A cheap supply of electrical power ought to enable many of our export industries to compete successfully in the world's markets. The project, therefore, is of national importance and ought to be discussed from a national point of view. In all problems of this nature, however, the 'human factor' has to be considered.

In the Bill, provision is made for the establishment of a Central Electricity Board which will consist of a chairman and seven other members. The main duty of this Board will be to supply electricity to authorised undertakers, but it will only generate electricity in exceptional cases. One of the first duties of this Board will be to submit to the Electricity Commissioners a scheme which will state what generating stations, existing or to be built, will be 'selected stations' for supplying electricity for the purposes of the Board. The Board is to provide for interconnexion of selected stations and authorised undertakings by means of main transmission lines which it will purchase or construct. It will also take means to standardise the frequency of the alternating current supply.

When the scheme is completed it will be published, and all persons interested in it can then be heard. The owners of supply stations affected have the right of appeal to the Electricity Commissioners, who have won golden opinions from every one in the past by the fairness and judicial calmness they have displayed when adjudicating on contentious matters. In the event of the owners and the Board failing to agree, the Board will have the right to acquire the undertaking. If no suitable authority be found willing to operate it, then the Board itself can make arrangements for carrying on the work.

The owners of selected stations are to operate as the Board may direct and are to sell to the Board on specified terms. The Board has to construct and lay down the mains and transmission lines which are requisite for purposes of interconnexion. It has also to supply the authorised undertakings at a price fixed so that the receipts may cover the expenditure when taken over a number of years. The tariff will be a 'John Hopkinson' tariff, consisting of two parts, a fixed charge and a charge depending on the load. If any authorised undertaking refuses to accept the Board's terms, then the Board has power to compel the undertaking to supply the consumer at the same rate as if it purchased its supply from the Board.

Roughly speaking, the Government has in view the selection of several highly efficient large power stations which will supply over transmission lines, belonging to the Electricity Board, to industrial centres. The small generating stations in these centres which now convert the heat obtained from the combustion of coal into electricity with a low efficiency will cease to be generating stations and will become merely distributing centres.

In order that the distribution may be done economically, it is certain that very high voltage must be used. The fixing of this voltage will be one of the first duties of the Board. Probably 110,000 volts will be chosen for the pressure of transmission, and the system adopted will almost certainly be the three-phase system. Except in the proximity of towns, the three large copper or aluminium conductors will be suspended from lattice steel towers at a considerable height from the ground. These steel towers, with wires suspended between them, are not beautiful, but they will not spoil the landscape so much as railway lines do. They will take many months to complete, and so perhaps it is necessary to state that the public should not expect any immediate reduction in the price of electricity.

The success of the scheme depends largely on the constitution of the first Board. We hope that some of the members will be young electrical engineers who have had experience of high-tension work in other countries. One also should be an expert in underground cable work, with first-hand knowledge of the maximum electric pressures that can be used in underground work. The questions of the maximum economy of transmission which are essential to the success of the scheme can only be solved by advanced mathematics and engineering intuition. The latter is necessary, as unfortunately we cannot foretell what will be the best distributing points ten years hence. In engineering it is sometimes necessary to make rapid decisions on insufficient data and to move forward warily, always being ready to amend the scheme when unforeseen developments arise.

Luckily, most of our leading engineers are almost wholly engrossed by their work. They take pride not only in its excellence but also in the amount of work they can do. In this respect they are unlike their humbler brethren, who are sometimes dominated by their fellow-workmen so that they are afraid to do their best or work their hardest.

Difficulties common to every great scheme for improving industry will doubtless arise. Certain engineers will have their stations 'selected,' others equally capable will be left in the humbler ranks of the distributors. There are many capable electrical engineers who have been working for the last ten or twenty years converting unprofitable supply undertakings into profitable ones. They have laboured well and hard and have exercised thrift in every possible direction. Plant laid down twenty years ago is still in excellent working order, although naturally it is not nearly so efficient as large modern plant. Other stations are burdens either on the shareholders or the ratepayers. Engineers have scrapped plant from which they were unable to get the maximum output or make work economically. New plant has been purchased, the thermal efficiency of which may meet the approval of the Board. Our sympathies are, however, with the hardworking and thrifty engineer, who, although he has made a commercial success of his undertaking, will doubtless in the future be merely a 'distributor.' It is sometimes truer economy to buy a set of cheap engines to help carry the 'peak' load than to buy a large turbine, with all its auxiliary plant, before it is really needed.

The new era, however, will give rise to new problems. Although we sympathise with those capable engineers, the importance of whose positions will be injuriously affected by the Bill, yet this is the way of progress. The Ministry of Transport has a heavy responsibility in appointing the new Board. Engineers who are familiar with the much less important problems arising in town distribution may not be the right men to handle the much graver problems which this scheme proposes. It is certain that, whatever system is adopted, it will in time become antiquated. It is necessary, therefore, to keep an open mind and to modify the system whenever by any means, present or future, economies can be effected by so doing.

Climate and Man in the United States.

The Climates of the United States. By Prof. Robert DeCourcy Ward. Pp. xvi + 518. (Boston, New York and London: Ginn and Co., 1925.) 4 dollars.

IN this work, Prof. Ward, the well-known climatologist of Harvard, gives us not merely a compilation of statistics relating to the distribution of the meteorological elements over his country, but to a very considerable extent, also, he exercises the true function of the climatologist in presenting vivid descriptions of climate, and its effects upon economic status and national life. The twenty-three chapters of the book, abundantly illustrated with charts and curves, including a handsome map of mean annual rainfall, discuss historical matter, the geographical controls of climate, the different types of climate met with in the United States, the regional and seasonal distribution of all the chief elements, namely, pressure, wind, temperature, humidity, sunshine, rain, and snowfall, etc., together with the relation of climate to crops and of climate to health. Thunderstorms and tornadoes, hot and cold waves, which are all in their great intensity characteristic American weather phenomena, come in for special discussion, as also 'blizzards,' Chinook winds (the föhn of the Rockies), and that peculiar phase of autumnal weather known as the 'Indian summer'—the great beauty of which in the eastern States is expatiated upon.

The use of the plural form in the title will be observed in regard to an area which includes a 'Mediterranean' type of climate on the Pacific coast, an almost tropical type on the shores of the Gulf of Mexico, an arid type in the Great Basin, semi-arid in the Plains, an extreme continental type with intensely cold winters, somewhat modified near the Great Lakes, along the Canadian border, and an Atlantic coast type which so far resembles the Atlantic coast of Europe as to have variable weather and a well-distributed, abundant rainfall. It must not be imagined, indeed, that we in England have any monopoly of changeable weather, for in New England the vicissitudes, just as frequent, are far more severe, and the New Yorker in winter time must be prepared for a change, within forty-eight hours, of, say, from +65° F. to −10° F., the like of which the Londoner has never dreamed. It is a little inconsistent, perhaps, to find the outlying Arctic territory of Alaska accorded the entire concluding chapter, while Cuba and the Sandwich Islands, also politically American, receive no mention—even though the Philippines, which physically belong to Asia, might well be excluded by reason of distance. The intense 'cold waves' of the north-east States are stated to occur between December and March, and the insufferable 'hot waves' between June and September; but we think that November and May, respectively, ought to be included within these periods. Certainly in Europe the frosts of November and the heat-spells of May are already very emphatic.

We have only one serious charge to launch against this excellent book, and that is a certain backwardness of outlook, noticeable especially in the entire omission of any reference to the modern theory of the polar front. In the constant emphasis laid upon the violent changes of temperature which mark the passage of the great winter cyclones across the northern tier of States, as the wind shifts from a warm to a cold quarter, every meteorologist, certainly in England, will recognise that the United States is the very country where 'discontinuities' between 'equatorial' and 'polar air' attain their sharpest development, associated with intense cyclonic activity in winter, along the Great Lakes, in New England and Nova Scotia, as currents of warm, damp air from the Gulf of Mexico and the Gulf Stream interact with supplies of intensely cold, dry air from the interior of Canada, along the so-called polar front. It is not that the theory of the polar front is by any means the last word in the dynamics of cyclones; what makes the omission serious is that the theory furnishes a common-sense, geographic background of reference in studying the interchange of air between the equator and the poles that has made more powerful appeal to the imagination than any idea in meteorology for a long time. We hope, therefore, that in a second edition the facts of climate which illustrate this theory so forcibly in America will be translated into a terminology which has by now passed into common use by British and Continental meteorologists, and is certainly familiar in the United States itself.

We could wish in this, as in many other works, for a rather more instructive systematisation and categorisation of the geographical factors which control the distribution of climate. The geographical distribution of climate is determined by (*a*) latitude; (*b*) altitude; (*c*) a highly complex, interdependent set of factors connected with the distribution and character of land, water, snow, and ice comprised under the designation 'continentality and oceanity'; (*d*) mountainous configuration (as distinct from mere altitude) affecting rainfall and exposure to wind, sun, and frost. Now it is quite impossible to class prevailing winds which transfer continental conditions seawards (as in the eastern United States) and oceanic conditions landwards (as in the British Isles) other than as a sub-factor of (*c*). This emerged with unmistakable clearness at a fairly recent discussion of Spitaler's Continentality maps. (See *Geographical Journal*, July 1924.) Imagine a *uniform* globe, divested, that is to say, of all differential effects of land and sea, and of polar ice: it is clear that over such a surface the undisturbed planetary winds could produce no local climatic differentiation, that air currents changing latitude would, on the average, quickly readjust their temperatures, and that if any cyclonic eddies developed along a poorly marked polar front, they must be very different in character from those with which we are actually so familiar. In fact, on a uniform earth, factors (*c*) and (*d*) above, being obliterated, and (*b*) only existing with regard to the free atmosphere (since *ex hypothesi* there are no vertical inequalities), climate would be a function of (*a*) alone, as regards, at least, its geographical distribution.

In the United States, the planetary westerly winds normal to the latitude are powerfully affected by the monsoonal influences of the North American continent, being twisted over the eastern States into prevailing south or south-west winds in July, and north-west winds in January.

There is no better chapter in the book than that dealing with climate and health, together with the summer and winter health resorts of the United States; and we do not think that any member of the medical faculty could find fault with the philosophy displayed. It is clearly recognised that climate to a considerable extent acts indirectly on the human organism, and that the same phases of weather and climate may produce effects variously, for good or evil, according as hygienic, economic, and social factors are sound or faulty, and according to the level of health of the individual. In England, for example, we know that a spell of frost and snow sends up the crude death-rate, but we also know that the same weather is a fine tonic to those who can react to it and love the open air.

L. C. W. BONACINA.

The Psychology of Selecting Men.

The Psychology of Selecting Men. By Prof. Donald A. Laird. Pp. xii+274. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 15*s.* net.

ENGINEERS and chemists have long been an essential part of the staff of every large factory. No new machine is bought before it has been carefully examined and good proof evinced of its worth. Samples of raw materials are analysed by the chemists to observe their purity or strength. It is but recently, however, that the importance has been realised, in full, of the scientific selection of staff. The success of many a factory depends as much, or more, on the skill of the men who use the machines as on the machines themselves. It is no uncommon thing to find two operatives with equal experience, working side by side on similar machines, one of whom will produce half again as great an output as his companion.

How can selection be successfully made among applicants for a position? What method can be used to gain a true indication of their innate capacity for the work? Dr. Laird in the work before us has answered this question with as much detail as is at present available. His book is admirably planned. He starts by outlining the need for employment psychology, and then proceeds to show how its basis rests on the degree and extent of individual differences, and how it is generally safe to postulate that in an unselected group of individuals, these differences approximate to normal distribution.

The validity of the older methods of selection—the letter of application, the interview, the so-called "scientific character reader"—is discussed, and Dr. Laird gives definite proof that their selective value in many cases, especially with young workers, is little better than that obtained by chance. The unwary reader is himself trapped into making judgments from handwriting and photographs and thus shown his limitations. Many factors are concerned in the inadequacy of these methods. Often they measure irrelevant factors—you can tell but little of a prospective engineer's ability from his conversation, or of a carpenter from the letter he writes. But even in cases where the methods themselves have potential prognostic capacity, this is often lost through slipshod application, and lack of a standard by which to judge the results.

All this, however, is by way of introduction; though useful as a warning, it is merely negative criticism. The second half of the book is more constructive. There Dr. Laird is concerned with the use and evaluation of psychological tests of selection. Almost any sort of task can be used as a test if only it will give an accurate indication of the applicant's ability, or predict with great success his future performance. There is, as Dr. Laird says, no mystery about mental tests. "They are simply an application of the scientific method." The tasks, whether they are actual samples of the work, or simple trials of the fundamental capacities underlying ability at the work, must prove their worth before they are used. "They must show their consistency from day to day, their consistency from user to user, and their internal consistency of measuring what they aim to measure."

It must be remembered, however, that "tests are part of employment psychology, but by no means are they the sole contribution of psychology to employment." The interview and letter of application can be improved by making them more objective and supplying standards. It is especially important to analyse the personal data of successful and unsuccessful workers by group comparisons or other methods, to discover if there are any distinct differences in such matters between the two groups.

Dr. Laird's book is, as he says in his preface, "a product of necessity." The demand among employers for scientific assistance in the selection of their workers is becoming pronounced, perhaps even more in Great Britain than in America. The subject is still in its infancy and an enormous amount of research is necessary, but already psychological tests have proved themselves more than idle theory, and are in use in many offices, shops, and factories. They have been approved of alike by the employers who have benefited by the increased output, and by the employees who appreciate the justice of this method of selection. With such economic and social value their future is assured.

W. SPIELMAN.

Astronomical Physics.

Astronomical Physics. By F. J. M. Stratton. Pp. xi+213+32 plates. (London: Methuen and Co., Ltd., 1925.) 12*s.* 6*d.* net.

WITH the whole universe for its field of inquiry, astronomical physics is necessarily a very large subject, and an attempt to present its methods and results in a single volume of modest size can scarcely be expected to satisfy the requirements of all classes of readers. In some respects, however, the author of the book before us has achieved his task with distinct success. In the space of two hundred pages he has covered the whole range of astronomical physics from its beginnings to the most recent speculations in cosmogony, and we have failed to notice any subject of importance which has not received some mention.

The author's aim has been "to provide a useful book on the subject for the student, and one which every astrophysicist and not a few spectroscopists would want constantly within reach," and he has endeavoured to compensate for brevity of treatment by giving an abundance of references. As a guide to original sources of information the book will certainly be of great value to actual workers in astronomical physics, and to all serious students of the subject who have access to a suitable library. Physicists desiring to become more closely acquainted with the inter-relationships of physics and astronomy, which are becoming more and more numerous, will also find the book of great service, and to them it may possibly not appear to suffer from undue compression. It seems unlikely, however, that the book will appeal to the general reader, for whom it is to be feared that much of the text may be too sketchy for intelligibility. One wonders, for example, how such a reader would fare in trying to interpret the photographs showing Zeeman effects in sunspots (Plate 17) from the few lines of description which accompany them.

Historical references, instruments, and laboratory investigations form the subjects of the earlier chapters, and these are followed by others on the sun, the solar system, stellar radiation, motion in the line of sight, stellar classification, giant and dwarf stars, nebulæ, novæ, variable stars, stars with peculiar spectra, and, finally, by a chapter on speculations in cosmogony. Among the subjects most fully dealt with are the criteria for the various groups of the Harvard classification of stellar spectra, and the determination of the orbit of a spectroscopic binary. Misprints are very few, but attention may be directed to the unfinished deduction of the formula for the Doppler displacement on p. 83 and the necessity for substitution of u for u/c in the last equation.

The thirty-two plates which illustrate the volume have been well chosen and are satisfactorily reproduced. Diagrams are only four in number, and additional ones might have been introduced with advantage, as, for example, light-curves of typical variable stars. A number of useful tables, including standard wave-lengths, are given as appendices. It is difficult, however, to see the application to the subjects dealt with of the table for correcting wave-lengths to vacuum; a list of bright stars with particulars of their spectra and other characteristics would have been of greater interest.

As a summary of the main facts of astrophysics, and as a reminder on problems awaiting solution, the book is a welcome addition to the few works on the subject at present available.

Conduction in Nerves.

The Theory of Decrementless Conduction in Narcotised Region of Nerve. By Prof. Genichi Kato. New edition. Pp. v+166+6 plates. (Tokyo: Nankōdō, Hongo, 1924.) 3 dollars.

UNTIL Prof. Kato had contributed this most important monograph to the study of the nervous system, it had been held generally that a nerve impulse passing through a length of nerve which had been rendered un-normal in some way, as by the action of narcotic drugs, underwent a gradual diminution in its course ('decrement'), leading, if the narcotised region were sufficiently long, to its complete extinction. If the impulse did regain normal nerve without suffering extinction, it regained its normal magnitude to the full.

The author contends that this view is erroneous. He and his colleagues in Keio University have used in their experiments a sciatic-nerve-gastrocnemius-muscle preparation which is 10 centimetres long, obtained from the Japanese toad *Bufo vulgaris Japonicus.* Such a preparation may be put in a narcotising chamber without fear of diffusion from the outside—and consequent dilution of the narcotic—upsetting the narcosis of the region observed. By varying the length of the chambers and the narcotising solutions or vapours therein contained, or by observing the electrical responses from narcotised nerve, evidence is produced against there being a gradual diminution. The impulse is subnormal but it does not suffer 'decrement.' On reaching again un-narcotised nerve, the impulse becomes normal. When the degree of narcosis is pressed, excitability and conductivity disappear simultaneously.

The unusual length of nerve in the Japanese toad gives also latitude for observations on the spread of current along the nerve, which may be for a distance so great as 2 cm. This is claimed as another source of error which workers with nerve-muscle preparations of only European magnitude cannot avoid. In the array of careful experiments described in detail with their protocols are some in which the conditions simulated those of earlier workers, who of necessity have used smaller animals than the Japanese toad. Then the results agree, until, altering conditions and avoiding the error of diffusion in narcotisation and of escape of current, as is possible with the great length of nerve, it is shown that no interpretation involving decrement of the impulse can be permitted. On other aspects of the passage of the impulse in nerve there is no wide disagreement with previous observers.

There are many small printing errors. On p. 79, "entangled" for "disentangled" or "untangled" is probably the worst. The book deserves an index.

These small failings will not detract from the far-reaching possibilities of Genichi Kato's work and inspiration.

Our Bookshelf.

The Fight for Everest: 1924. By Lieut.-Col. E. F. Norton and other Members of the Expedition. Pp. xi+372+32 plates+2 maps. (London: Edward Arnold and Co., 1925.) 25*s*. net.

It would indeed be a strange personality which would not be stirred by this thrilling account, ending, alas, in tragedy, of the third expedition towards the summit of Mount Everest. The first in 1921 was in fact no more than a reconnaissance, the second in 1922 is described as "The assault," while we may well hope that the 1924 volume now published under the title of the "Fight for Everest" will be itself succeeded by the final volume, the "Attainment."

The introduction by Sir Francis Younghusband should persuade even the most cold-blooded reader of the value of such an effort. Most of the members of the expedition contribute a chapter or more: commencing with "The Start," by General Bruce, soon to be invalided back to the base and to be succeeded in command by Colonel Norton, there follow in succession (an enumeration of the chapter sub-titles tells the story), the march across Tibet, the Rongbuk Glacier, the North Col, Norton and Somervell's attempt, Mallory and Irvine's attempt, the return to Base Camp.

Mallory's letters, too, are fascinating reading, giving a glimpse of that enthusiasm which carried him and Irvine to their last final climb. The actual cause of their deaths will always remain a mystery. Did they reach the summit and fail to find their camp again or did they meet with an accident? We sympathise with the relatives and friends of those who died, a sympathy mingled with pride that Britain can still produce these men.

Second only to the last climb are those of Norton and Somervell and of Odell; a height of 28,000 feet seems well within the reach of such men, while it seems only a few years ago that a climb to 24,000 feet was considered an impossibility.

Part III. deals with the scientific results, the physiological effects, and the use of oxygen, as well as the natural history, geology and glaciology and photography, each of which are well treated.

Although newspaper articles and the well-known cinema, the "Epic of Everest," have familiarised us with most of the details of the expedition, this volume forms a valuable permanent record, well illustrated as it is with an exceptionally artistic map.

Landmarks in the Struggle between Science and Religion. By Prof. James Y. Simpson. Pp. xiv + 288. (London: Hodder and Stoughton, Ltd., 1925.) 7*s*. 6*d*. net.

One may surmise that in writing this book Prof. Simpson had in mind the religious layman rather than the scientific man, who will, we fear, find the discussions of early theology, especially in the first half of the book, somewhat wearisome. Prof. Simpson covers a very wide field, in theology, pre-history, science and philosophy. His book is erudite and well documented, and indicates a remarkably wide acquaintance with many extremely diverse branches of knowledge. There is, however, a certain disjointedness in the treatment of his almost superabundant historical material, which does not make for easy reading, nor is his central theme of the struggle between science and religion developed in any sustained and systematic way.

This said by way of criticism, we must remark on the competence and open-mindedness of the author's handling of a difficult and controversial subject. His attitude is that of a deeply religious man who is not afraid to accept all the well-substantiated results of science, and is able to harmonise them with his own beliefs. His position is that "Science describes, the philosophy of science explains, and religion interprets; and description, explanation, and interpretation are alike elements in the process of man's mental and spiritual adjustment or adaptation to the Universe. Each is necessary, the one to the other, and must enter into any intelligent understanding of the world as a whole. Science leaves us with descriptions which philosophy explains in terms of a phenomenal dynamic Universe; religion interprets the whole most satisfactorily, after an examination of all other interpretations, as the self-expression or unfolding of the activity of a creative God" (pp. 270-71).

We take it that science has no real quarrel with religion, as a certain attitude to the universe, but only with the accretions of dogmatic theology. That science had a hard fight to free itself from the trammels of theological and other dogmatic thought is made abundantly clear in Prof. Simpson's book, and vigilance is still necessary to preserve this hard-won freedom. But it is well to remember that the scientific man must beware of dogmatism also in his own sphere; he must continually test and criticise accepted theories lest they become dead and traditional; and he must guard against the danger of erecting a convenient method of science into a philosophy of life. E. S. R.

L'Adaptation. Par Prof. L. Cuénot. (Encyclopédie scientifique: Bibliothèque de biologie générale.) Pp. 420. (Paris: Gaston Doin, 1925.) 20 francs.

PROF. CUÉNOT has done biologists a service in writing this book. It contains treasures of knowledge, which have been treated with great skill and acumen.

Especially valuable, perhaps, are the sections distinguishing the different types of adaptation (necessary and sufficient adaptation, statistical adaptation, etc); those dealing with the important but limited rôle of what is usually called pre-adaptation; the assemblage of interesting facts on co-adaptation; the section on adaptations which are analysable into individual modifications and germinally-determined characters both acting in the same sense; and that on the reason for the rarity or absence of primitive and intermediate types.

Prof. Cuénot is perhaps less good on the bearing of mutations on the problem. It is difficult to see why he regards natural selection as only weeding out mutations which depart from the type: Why should not the neo-Darwinian scheme work with mutations as its raw material? Also, in his discussion of orthogenesis and co-adaptations, he often forgets, or seems to forget, the important fact that an organism's environment is largely composed of other organisms, and that therefore we should expect to find an improvement in one organism bringing out improvements in another, as improvements in naval guns brought out improvements in armour plate and vice versa. This principle will at least help to account for many (though probably not all) of the simultaneous, slow, 'orthogenetic' lines seen in palæontology. He could have accounted for some other orthogenetic phenomena by reference to the mechanisms of heterogonic growth (as summarised by Champy in his "Sexualité et Hormones").

Prof. Cuénot is sceptical as to the value of any of the existing explanations of adaptation, whether by Lamarckian means, by slow selection, by large mutation, or by predetermined orthogenesis. However, whether we share his scepticism or not, he has here provided considerable food for thought on one of the central problems of biology.

Penrose's Annual: the Process Year Book and Review of the Graphic Arts. Edited by William Gamble. Vol. 28, 1926. Pp. xvi + 146 + 70 + 57 plates. (London: Percy Lund, Humphries and Co., Ltd., 1926.) 8*s*. net.

THE editor, in his usual review of process work, says that he regretfully confesses that the year 1925, the end of a quarter century, shows "no new process, nor change of method, which is of outstanding importance; nothing, in fact, that could be regarded as a milestone of progress passed in the onward march of our art and craft." Much is being done, but it is in continuance of work started in previous years, especially since the War, and it may be expected to bear fruit in the immediate years to come. The editor then describes the remarkable progress that has been made during the quarter of a century just completed, which includes the introduction of the offset method and rotary photogravure. Colour gravure, based on three-colour principles, is making great headway, and an example is given of a flower study reproduced by this process, and also by a letterpress method from four blocks, so that the two results can be compared. Collotype is still printed on slow-running flat-bed machines which are turning out excellent work, and "it hardly seems likely that this practice will ever be altered." The progress of the various methods of replacing the ordinary type setting of text by photographic methods are passed in review, but it seems that none have yet convinced the printing trade of the advantages of these inventions over existing methods.

The text consists of 34 articles by experts, who give experiences or data of value. The curious chemical equation at page 129 shows that practical men should be content to leave theory to those that understand it. The fifth of the series of "The Work of the Private Presses" is by Mr. Chas. T. Jacobi on the Eragny Press, 1894–1914, and is illustrated with specimens. The numerous plates may be considered as showing the best that can be done to-day by perhaps every process that is in use.

A System of Physical Chemistry. By Prof. William C. McC. Lewis. (Text-Books of Physical Chemistry.) In 3 vols. Vol. 2: Thermodynamics. Fourth edition. Pp. viii + 489. (London: Longmans, Green and Co., 1925.) 15*s*. net.

THE third edition of Vol. 2 of Lewis's "Physical Chemistry" appeared in 1920, and included 445 pages of text. The fourth edition has been increased to 481 pages, mainly by the inclusion of half a chapter on "The Activity Theory of Evolutions" and half a chapter on "The Milner-Debye Theory of Strong Electrolytes." In accordance with the author's policy of quoting extensively from original sources, the latter section is taken from a paper by A. A. Noyes which appeared in the *Journal of the American Chemical Society* in 1924.

British Birds. Written and Illustrated by Archibald Thorburn. New edition. In 4 vols. Vol. 2. Pp. ix + 130 + 48 plates. (London: Longmans, Green and Co., 1925.) 16*s*. net.

THE first volume of the new edition of Mr. Thorburn's "British Birds" has already been noticed in these columns (September 12, p. 390); the second of the four has now appeared. The coloured plates are again very beautiful, but the amount of space given to rarities, in text and picture, continues to keep the treatment of more important birds within rather narrow limits. One is glad to note, however, the figuring of so many as three plumage-phases of the great spotted woodpecker, and that the immature plumage of the gannet is also shown.

Laboratory Manual of Elementary Colloid Chemistry. By Emil Hatschek. Second edition. Pp. 153. (London: J. and A. Churchill, 1925.) 7*s*. 6d. net.

THE second edition of Hatschek's "Laboratory Manual of Elementary Colloid Chemistry" contains new chapters on "Oxide and Hydroxide Sols" and on "Non-aqueous Emulsoid Sols and Gels." Methods for determining the coagulation velocity and for demonstrating the variation of viscosity with rate of shear have also been included.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Light Quanta and Photo-electric Emission.

I VENTURE to think that no theory has suffered so much from the application of an arbitrary selection principle to the consideration of experimental results as the quantum theory. The treatment of the whole subject, at least so far as it is concerned with X-ray phenomena—and in no branch of study is the acquaintance with the quantum rules and with their limitation so intimate—is based upon a very inadequate knowledge of facts. It could scarcely be otherwise when experimental acquaintance with the subject is so meagre For the present I should like to mention only one point.

The 'light-quantum' theory receives its strongest support in the phenomenon of electron emission when radiation is absorbed It is thought by some—apparently by many—that the "light-quantum" retains its individuality between the process of emission and that of absorption. May I then record an experimental fact bearing upon the subject?

The ionisation produced by a heterogeneous beam of X-rays in a gas or the electronic emission from a metal plate (measured by ionisation outside the plate) may be abruptly and enormously increased either by (*a*) superposing on that beam a very feeble radiation of slightly shorter wave-lengths, or (*b*) by taking away from the complex radiation a very small amount of the radiation of longer wave-lengths as by filtering; that is, either by adding higher frequency radiations to, or eliminating lower frequency radiations from the beam, the same effect is produced, namely, a sudden large increase in the ionisation. The magnitude of a sudden increase may be from 100 to 150 per cent of the original magnitude. This is the *J* ionisation produced by the *J* photo-electric emission accompanying the *J* absorption. Where then are the discrete and independent quanta?

These experimental results again show quite definitely that this *J* electron emission is an effect of the radiation as a whole. The quality of the full stream of radiation decides whether or not this shall take place. It appears (though this is much less certain) that the absorption is an absorption of all the constituents.

Such results were obtained by Miss White and myself six or seven years ago, but were withheld from publication until they could be confirmed by many experiments such as we have recently recorded (and others at present being obtained by Miss Mair), showing that these form part of a consistent whole. If then a small-angled prism of aluminium—a wedge—is placed in the path of a heterogeneous beam of X-rays, there is transmitted a spectrum of radiations varying in *average* wave-length, capable of showing both *J* absorption lines and *J* absorption edges by the ionisation method, as do homogeneous radiations. The phenomenon is now being studied photographically.

Eka-cæsium and a Suggestion about Radiation and the Elements.[1]

IN endeavouring to confirm the identity of the X-ray line 1·032 on Film No. 3 (see NATURE, January 30, 1926, p. 153), which would seem to correspond with the La_1 line of eka-cæsium (87) of calculated wave-length 1·0276, I have had this film intensified and then remeasured by Messrs. Adam Hilger, Ltd. (see *Chemical News*, February 12, 1926, p. 101).

The result is that the lines which according to the original measurement were 1·434, 1·232, and 1·032 now measure 1·434, 1·234, and 1·029, thus confirming the first values obtained, as it must be remembered we are not able to determine the lines very accurately, there being a possible error of 0·005, as previously stated.

The strong line of mercury, $L\beta_1$ of wave-length 1·0458, seems, however, to be ruled out, unless something has happened to the film originally. I understand that films on development tend to shrink rather than to stretch. This would not satisfy the suspicion that the line attributed to element 87 is the mercury one in question. There seems to be no other alternative than that the line is 87 La_1. More work in this field is obviously necessary.

Unfortunately, the first experiment cannot be repeated with the present apparatus, as there is now very little of the original material prepared by Dr. J. G. F. Druce.

Glass photographic plates are now being used in order to ensure greater accuracy, especially in measurement.

The question whether such elements as 85 and 87 can exist without being appreciably radioactive has been considered. There are several well-known instances of comparatively stable and even non-radioactive elements having the same atomic number as those which are very unstable, and uranium, the last-known member of the general series, is far more stable than most of those elements of somewhat lower atomic number. Therefore there is no absolute criterion as a guide in this respect.

Potassium and rubidium are feebly radioactive, but, curiously enough, no products from their radio-change seem to accumulate—at least, not so far as I know. If these common elements are contaminated with those of atomic numbers 85 and 87, and if these are radioactive, then the problem would only be partly solved. There is, however, no evidence of this kind. Both elements are mentioned on account of some statements to follow here

Those elements of high atomic number are unstable and they emit corpuscular radiation and electromagnetic radiation; that is, α-, β-, and γ-rays, with variations according to the radio-element considered.

Conversely, one might think of the elements at the other end of the general series as having absorbed such 'radiation' at one time in their history, and thereby growing into larger and larger atoms, as are now known. Blackett's well-known experiments on the disruption of the nitrogen atom by high-speed alpha particles, as previously accomplished by Rutherford, further reveal photographically, by using the C. T. R. Wilson ionisation cloud method, that when an H-particle (proton) is ejected from the nitrogen nucleus, the bombarding alpha particle, which caused the ejection, becomes absorbed in the nitrogen nucleus. Henderson's experiments indicate that capture and loss of electrons by alpha particles is also a process which comes under the general head of *mass absorption and mass radiation.*

---

[1] The word radiation in this title is here used more particularly in the sense of *corpuscular* or mass radiation.

There is a further consideration: one might ask whether there could be a half-way state in which some elements spontaneously carry out both processes; that is to say, they absorb "radiation" and then emit it in the radioactive manner, as distinguished from the photoelectric effect proper. Some further statement seems necessary here, since at best the idea may only be a half-truth.

However that may be, this idea is suggested by the fact that potassium and rubidium spontaneously emit electrons (β-rays). Have we here the intermediate type of activity hinted at above? If these elements could absorb and then re-emit electrons, the process repeating, their radioactivity would be accounted for without the accumulation of disintegration products Furthermore, this dual process may reside in an impurity (elements) present in potassium and rubidium.

Considering again the experimental side, I have succeeded in exposing normal manganese phosphate (Kahlbaum's) for 10 hours without getting anything on the photographic film other than the copper lines (including a faint satellite in connexion therewith) and two almost invisible lines of wave-lengths 1·433 and 1·233. It would appear that these were the $L\alpha_1$ and $L\beta_1$ lines of element 75 of calculated wave-lengths 1·4298 and 1·2358. Berg and Tacke (*Naturwissenschaften*, 1925, 26, p. 571) calculate the values respectively as 1·4306 and 1·2355. The range of exposure was from the silver absorption edge to the copper $K\alpha_1$ and $K\alpha_2$ lines, which were, by the way, resolved. There was a good deal of phosphate on the anticathode I believe this experiment shows good technique Whether the above pair of exceedingly faint lines were those of Zn$K\alpha_1$ and $K\alpha_2$ combined, and Hg$L\alpha_1$, is partly immaterial to the present argument, for it suggests that it would be worth while examining potassium and rubidium in this way in order to detect if possible traces of, say, 87 in one of them.

This work is now in hand and the technique is steadily being improved. In these experiments the cathode should be in good condition; that is, not bored out by the anode rays.

The wave-lengths given above are in Angström units as before.

F. H. LORING.

The Magnetic Moment of the Orbit of the Valency Electron of the Solid Alkali Metals.

THE normal state of the atoms of the vapours of the alkali metals is an '*s*' state, the atoms consisting of a rare gas core round which revolves the valency electron in a n_1 orbit (4_1 for potassium, 5_1 for rubidium, 6_1 for cæsium). One would then expect that the vapours of these elements would be paramagnetic and that, when the diamagnetic properties of the rare gas cores were allowed for, a magneton number would be found corresponding to 1 Bohr magneton or 8·6 Weiss units. Data as to the magnetic properties of these vapours are apparently wanting, but the spectroscopic evidence leaves no doubt as to what is to be expected.

It is of some interest to see how far these predictions can be extended to the case of the solid state and what information the magnetic measurements can provide as to the nature of the atoms in the solid. If the lattice of the latter were built up of atoms in the same state as those of the vapour, one would expect that the metals would be paramagnetic, would follow the law $\chi(T+\Delta)=C$, and that, supposing Δ to have a value of the order usually found, the atomic susceptibilities of all the alkali metals would lie round about $+1300 \times 10^{-6}$.

If, on the other hand, there is a non-polar linking between the atoms of the solids, the valency electrons being shared by neighbouring atoms, one would expect that the total magnetic moment of the orbits of the valency electrons would be zero or nearly so on account of the complete or approximate compensation of the actual moments of the pair of shared orbits. The valency electrons would then contribute at most a small positive amount to the total moment of the atom and the substances would be diamagnetic. Probably, too, these shared orbits would not take a definite part in the thermal agitation of the atoms, and their positive contribution to the susceptibility would be independent of the temperature.

Further, it would be expected that the closest distance of approach between atoms of the solid alkali metals would then be smaller than the largest dimension of the n_1 orbit and larger than the radius of the rare gas core

The experimental data for the susceptibilities of the solid alkali metals have until recently been somewhat chaotic. Recent measurements by Miss Crow (*Proc Roy. Soc. Canada*, 19, 63, 1925) seem to be more satisfactory. The susceptibilities of solid potassium, rubidium, and cæsium, together with the contributions to the susceptibilities due to the rubidium and cæsium ions were measured with the following results: atomic susceptibilities K $-1{\cdot}9 \times 10^{-6}$, Rb -7×10^{-6}, Cs -8×10^{-6}, Rb$^+$ $-29{\cdot}8 \times 10^{-6}$,[1] Cs$^+$ $-37{\cdot}4 \times 10^{-6}$. We may add the value $-16{\cdot}4 \times 10^{-6}$ for K$^+$, being the mean of the figures given by Pascal (*C.R.* 158, 37, 1914) and Joos (*Zeits. f. Phys.*, 32, 835, 1925).

We thus see that the contributions to the susceptibility of the valency electrons are as follows: K $+14{\cdot}5 \times 10^{-6}$, Rb $+22{\cdot}8 \times 10^{-6}$, Cs $+29{\cdot}4 \times 10^{-6}$. A small correction for the diamagnetic properties of the actual orbit of the valency electron has still to be applied, but the values will remain of the same order of magnitude. It will be seen that these values are very much smaller than what would be expected for a normal n_1 orbit, but are of the order one would expect for the residual moment of nearly completely compensated shared orbits

The contributions of the valency electrons to the atomic susceptibilities are approximately in the ratio $4^2 : 5^2 : 6^2$ for K, Rb, Cs.

The susceptibilities of the solid alkali metals are also apparently independent of the temperature, and the closest distance of approach of the atoms in the lattice falls in between the values for the major axis of the n_1 orbit and the radius of the rare gas core, being 2·25 Å.U, 3·2 Å.U., and 1·55 Å.U. respectively for potassium.

Measurements of the magnetic properties of the alkali metals would thus indicate that the orbits of the valency electrons for the solid state are not the independent n_1 orbits shown by the spectroscopic data, but are shared by the neighbouring atoms to form a non-polar binding

Chemical Effects produced by Resonance Radiation.

WE have read with interest the communication of Prof. H. S Taylor and his collaborators on the subject of chemical effects produced by resonance radiation, in which some exception is taken both to our experiments and to the conclusions given in our letter of December 19, p 899. It may be as well to indicate briefly the points on which we are in agreement and those on which a divergence of opinion apparently exists.

---

[1] There appears to be an arithmetical error in the paper referred to, the mean for A/B being 449 and not 451, so that the susceptibility of Rb$^+$ is $-29{\cdot}8 \times 10^{-6}$ in place of $-29{\cdot}9 \times 10^{-6}$ as actually given.

It is generally agreed that the reactions under consideration involve the photosensitisation of mercury atoms, which on impact with hydrogen molecules render these in some way active for combination with gases. In our view, these reactions involve the simple addition of active hydrogen molecules to molecules of the reactants such as O_2, N_2, C_2H_4, CO. In a recent communication to the Cambridge Philosophical Society, this view was supported by the isolation of H_2O_2, the first step in the formation of water, and of N_2H_4, the second step in the formation of ammonia. The presence of hydrogen peroxide we note has now been observed by Prof Taylor. On the other hand, from the Princeton communications we gather that they incline to the view that the processes involve a series of chain reactions in which atoms and unstable groups such as H, C_2H_5, OH play a part, the chains being started by one excited mercury atom.

The second point on which some slight difference of opinion exists lies in the relation of a liquid mercury surface to the progress of these reactions. We agree that the mercury atoms forming part of the liquid are not active in photosensitisation: in fact, the selective action of the light λ2537 indicates that the absorbing atoms must be free from all constraints. The divergence in view is therefore concerned rather with the distribution of active mercury vapour in the illuminated system, when reaction is proceeding, than with the fundamental mechanism of the process. In the flow method large rates of reaction are obtainable with a continuous supply of fresh mercury vapour, but in a static system the mercury atoms in the gas phase apparently only preserve their photo-sensitising power for a very short time. Prof. Taylor apparently believes that the liquid mercury serves no other purpose than to supply by evaporation the wastage of mercury atoms in the homogeneous gas phase caused by chemical combination, *e.g.* mercuric oxide. We can confirm this removal in the case of the hydrogen-oxygen combination. Since similar results are obtained for hydrogen and ethylene, chemical removal may not be the only method by which mercury atoms lose their photo-sensitising powers.

This removal or loss of potential activity must proceed so rapidly that after but a short period of illumination the gas phase is almost devoid of active mercury atoms, and practically all the chemical action is confined, at high gas pressures at any rate, to a thin layer in close proximity to the liquid mercury

Finally, one small point remains. From the Princeton letter it would appear that these various reactions were discovered there and that, after publication of their results, work was commenced at Cambridge on the same lines. Without the least intention of detracting from the interest and value of the communications from Prof. Taylor, to whom we are indebted for the suggestion of employing a water-cooled arc, we must affirm that neither of these conclusions can be considered as quite correct. Franck and his co-workers may well be claimed as the discoverers of these reactions. Whilst it is true that our first note on our experimental work was contained in the letter referred to above, the apparatus had been constructed for us by the Thermal Syndicate in 1924 for the purpose of investigating these very reactions. Our early experiments were extremely unsatisfactory owing to the weakness of the resonance line obtained with air-cooled mercury arcs, and it is to Prof. Taylor that we are indebted for the suggestion of water-cooling. We may add for the information of the many other workers in this interesting field that the employment of an electromagnet in addition to water-cooling, as suggested by Prof. R. W. Wood, leads to a very considerable augmentation in intensity of the resonance light.

The Subjective Analysis of Musical Tone.

EVERY one who has attempted to analyse a musical sound by the unaided ear and has acquired some experience at such work will recognise the peculiar nature of the difficulties met with. The first stage is, of course, to learn to concentrate attention on the particular partial sound sought to be recognised, and this is greatly assisted by previously sounding a note of the same pitch and firmly fixing it in the memory, as recommended by Helmholtz in his "Sensations of Tone." But even after one has acquired this habit of attention and has had years of practice and experience in acoustical work, the difficulty is only diminished and is not removed, as is shown by the fact that one may fail in some cases to distinguish a partial even if it be present, and that the use of a resonator is always a great advantage.

Helmholtz, in a chapter on the subject in his "Sensations of Tone," has discussed the difficulties experienced in the subjective analysis of sound at great length, and considers them to be the result of a natural tendency to fix attention on the synthetic rather than on the analytic characters of a compound sensation. This explanation is psychological rather than physical. That it does not go to the root of the matter is shown by a fact which Helmholtz himself mentions, namely, that it is easier to hear the unevenly numbered partials than the evenly numbered ones ; this suggests that we should seek for a physical and mechanical explanation rather than a psychological one. Further, it is possible to work under conditions which eliminate any explanation of the difficulty of subjective analysis as due to lack of attention When the observer has carefully prepared himself, as indicated above, *immediately* before an observation is made and his faculty of attention is at its highest level, he succeeds in observing the partial only in certain cases and not in others. From this, one may reasonably infer that the power of discrimination is limited chiefly by circumstances depending on the physical character of the sound and of the auditory mechanism of the ear, rather than by factors dependent on nervous perception.

Some observations recently made by me indicate that the difficulty felt in the subjective analysis of musical tone arises mainly, if not entirely, from the phenomenon of the masking of pure tones of higher pitch by those of lower pitch discovered by A M. Mayer (*Phil. Mag.*, **2**, 500, 1876), whose results have more recently been confirmed and extended by R. L. Wegel and C. E Lane (*Physical Review*, **23**, 266, 1924). Mayer discovered that sounds which are of considerable intensity when heard by themselves are liable to be weakened and even completely obliterated by graver sounds of sufficient force. The surprising character of this phenomenon must be experienced to be fully appreciated. That the auditory masking of pure tones of high pitch by those of lower pitch is the explanation of the difficulty felt in the subjective analysis of musical tone may be shown by simple experiments with a monochord. The observer selects a particular partial, say the 5th, for examination. By gently touching a node of this partial with one finger, and plucking the string repeatedly with another finger, the attention of the ear is fixed on the pitch of this partial. The damping finger is then removed, and the string is plucked sharply at a point not far from the end to elicit the full series of partials. The observer listens carefully for the 5th partial for a second or so, and then touches the string exactly at its node so as to damp out all the partials lower than the 5th. The 5th partial then sings out, and though theoretically its intensity should have been the same, actually a large *apparent* increase of intensity is usually perceived. The sound of the 5th partial, previously masked by the sound of the graver partials, asserts itself with vehemence when they are removed.

A further confirmation of these ideas is furnished by studies of the manner in which the audibility of the upper partials alters when the absolute intensity of the sound or its quality is varied. These details are reserved for consideration in a forthcoming paper.

Intensification of the Metallic Image in Gerlach and Stern's Magnetic Experiments.

IN the course of some attempts to measure the magnetic moment of the cadmium atom by a slight modification of Gerlach and Stern's original arrangement, a new method of intensifying the effect of a deposit of a very small number of metallic atoms on glass has been used, which although perhaps rather obvious has not, so far as I can ascertain, been employed for this purpose before. In Gerlach and Stern's first experiments on the silver atom a chemical method of rendering the deposit of atoms on the glass plate visible was used. In their later experiments on other metals it was found that in certain cases the deposit was visible without intensification, but in others it had to be developed by the same means. It is, however, plain that the use of comparatively huge quantities of liquid when dealing with a metallic deposit which may be at the most on the average only one molecule thick is dangerous, as solution of the deposit might easily occur. The method now to be described avoids this difficulty and is also probably easier to work. It depends on the fact that, while cadmium vapour at low pressures will not condense on a clean glass surface at ordinary temperatures, it does so readily at liquid air temperature. If, however, the smallest deposit of cadmium is already present on the glass, the vapour will condense on it at ordinary air temperature, quickly forming a visible deposit.

This phenomenon was originally discovered by Langmuir. He showed that by its use it was possible to obtain a visible deposit if only one cadmium atom per 3000 surface molecules of the glass was present. It is accordingly eminently suitable for our purpose. During the course of an experiment, the bottom of the glass flask on which the cadmium atoms impinge after passing through the magnetic field is immersed in liquid air. At the end of the experiment, to intensify the cadmium image, it is only necessary to remove the liquid air, allow the glass vessel to attain air temperature, and then evaporate a small quantity of cadmium inside the vessel by suitable means. The cadmium vapour will now only condense on the glass surface which has already a small trace of cadmium on it, and it has been found that a visible deposit quickly forms if any such trace is present. Blank experiments have also shown that if there is no cadmium originally present on the glass, no deposit will form. The pressure of the developing cadmium vapour must not be raised too high, as if this is done it may in certain circumstances condense on clean glass. In practice, however, it fortunately does not seem very easy to attain this state, especially if any metal objects are present in the vacuum, as the cadmium will readily condense on them, thus quickly lowering the pressure.

This method of intensifying small metallic deposits on glass can also be used in the cases of the other more volatile metals such as zinc and magnesium. It is also perhaps indirectly applicable to metals such as copper, which condense on glass at air temperature, as my experiments seem to show that cadmium vapour will condense on most metals at air temperature. Whether, however, a very few atoms of another metal will cause the cadmium vapour to condense I have not yet succeeded in proving, but on the whole the outlook seems hopeful. It is also possible that the presence of an electric charge on the surface of a quartz plate might cause condensation, but again this point has not been tried. However, without entering on these possible applications, it is evident that this method may be of great use in any experiments in which we have to deal with streams of either atoms or molecules the velocity of which is too low to affect a photographic plate, and the presence of which it is accordingly very hard to detect.

J. H. J. POOLE.

Physical Laboratory,
Trinity College, Dublin,
February 20.

Greenland or Polar Front?

No meteorologist could be less disposed than myself to underrate the importance of Greenland as a *factor* in determining the characteristic circulation over the North Atlantic Ocean, but I challenge the extravagant contention that cyclonic circulation, which is an integral part of the general circulation, depends *entirely* upon the "katabatic" operations of a relatively small and accidental feature in the configuration of the northern hemisphere like Greenland. To contend that the analogous Pacific centre of cyclonic activity, scarcely less intense than the Atlantic, is nourished by the same katabatic action of Greenland's ice-dome is surely out of the question.

Owing to pressure on space I cannot deal in any detail with the points raised in Prof. Hobb's letter to NATURE of February 13, but will briefly indicate the general line of reply. First of all, the discrepancy between the fact of relatively high pressure over the North Pole and the fact that the *Fram*, in the course of her drift in 1895 along the 85th parallel in the European sector of the Arctic, experienced a slight, 10 per cent, excess of southerly over northerly winds, can be reconciled by a closer study of Mohn's isobaric charts, which show a shallow elongation of the Icelandic pressure minimum north-eastwards towards Spitsbergen. With the trend of the isobars in this particular sector the slight excess of southerly winds recognised by Mohn himself is quite consistent But the major fact of the existence at all seasons of an "Arctic Wind Divide," shown by Mohn to lie across the polar basin between the Atlantic and Pacific minima, means that in the day-to-day changes there must be many occasions when air drains southwards over Europe whether reinforced from Greenland or not; and I am sure that any British weather forecaster will bear me out that there *are* many such occasions.

Secondly, the monthly distribution of the fog-frequency shows that only June, July, August, and September during the voyage of the *Fram* could in any sense be called foggy, the other eight months being, either absolutely or nearly, fogless ("Scientific Results of *Fram* Expedition," 1893–96, vol. 6, p. 572). But these fog statistics which Prof. Hobbs tries to turn in his favour have really little bearing on the argument at all, inasmuch as fog can exist at temperatures far below freezing; and, in any case, if fog-laden air moved outwards from the polar basin into warmer latitudes the moisture would soon be dissipated and the air become in perfect condition to form discontinuities with warm humid equatorial air along the polar front.

Thirdly, Prof. Hobbs is incorrect in underestimating the cold of the North Pole in winter, as Mohn's isothermal charts should convince him The Arctic Ocean in its outer portions is milder than the inner polar basin, and the fact referred to by Prof. Hobbs, that along the Arctic shores of Siberia and Canada southerly winds in winter are colder than northerly, is in accordance with the principle lately formulated by Dr C. H. Pollog of Munich, that where there is a sudden transition from land-ice to sea-ice, the air over the latter is warmer because heat is conducted upwards through the ice from the unfrozen water beneath (*Mitt. Geog. Gesell Munchen*, vol 27, No. 2, 1924).

Parasitism of the Dodder.

The paragraph on Dr. Thomson's interesting work (1925) in Nature of February 6, p. 210, contains a reference to the results of "earlier observers" which I cannot pass without comment

Thomson found no phloem in the haustorium of Cuscuta, either in the shaft or in the brush of hyphæ; and no special connexion to the phloem of the host, corresponding with the xylem connexions. But Peirce (1893) described and figured both xylem and phloem in the shaft of the haustorium. This phloem I also found (1911), and Zender, who is not here, as the writer of the note states, in complete agreement with Thomson, also refers to phloem that is "only found in the primary portion" of the sucker (*Inst. de Bot. Genève*, 1924, p. 9). This phloem is small in amount; the sieve tubes are rather short, but quite typical and like those in the main stem of Cuscuta. Peirce and I cannot have differed in our descriptions of the position of the phloem in the shaft, as I did not attempt to describe the anatomical distribution of the tissues either of the main stem or of the shaft of the haustorium.

My work concerned mainly not the above typical phloem in the shaft but the strings of short sieve tubes in the distal part of the haustorium of Cuscuta. Here there are no elongated sieve tubes with well-bored-out sieve plates. This part of the haustorium is formed from the brush of hairs or 'hyphæ' which originate from the tip and sometimes from the sides of the haustorium proper. Thomson and others before him have described the formation of strings of short xylem elements from some of these invading hyphæ. I find similar strings of short phloem elements (perhaps better called sieve elements than sieve tubes) developed from other of the invading hyphæ, nearer the periphery of the brush. There is no possibility of regarding these elements as other than phloem, as there are well-defined sieve areas in their walls; one cannot mistake a typical sieve area properly stained by the safranin and London blue method, each deep red string surrounded by its blue callus rod. The method cannot be used with material which has been in alcohol, and histological work of this kind requires, of course, very high magnifications and critical illumination.

Just as, where a 'hypha' becomes attached to a xylem element of the host, the cell walls of the hypha become lignified, so in a hypha which is attached to a host sieve tube the division walls of the hypha develop sieve areas. These attachments do not appear to be so numerous as those in the xylem, but I found them quite as definite in the species I studied as did Zender. The wall of the hyphal tip disappears and the naked protoplasm is applied to the host sieve plate. The further very elaborate behaviour of the protoplasm inside the cavity of the host sieve tube, which is described by Zender, has not been seen by me.

I have explained that the statement that Peirce and I are "not in agreement as to the position of the phloem" is based on a misapprehension I hope I have made it clear that the evidence of independent observers renders the assertion that "the earlier observers . . . were in error in reporting its presence" somewhat hasty, especially as it is not possible to judge of Dr. Thomson's methods.

Ozone and the Upper Atmosphere.

A benighted chemist, I listened with awe and interest to the discussion by the physicists on the electrical state of the upper atmosphere, on March 4, at the Royal Society. Apparently they were not quite at home above cloudland. The blessed word "ionisation" played a great part but did not seem to mean more than "conducting" Ozone was referred to with respect. Perhaps a chemist may be allowed to suggest a way in which it might serve as an "accumulator."

Those who attended the late Sir James Dewar's wonderful demonstrations at the Royal Institution may have witnessed the production of ozone, at the surface of liquid and even of solid oxygen, under the influence of ultra-violet radiation and will often have seen the glow of its decadence (to oxygen). Presumably, ozone is not the direct or immediate product of the action of such radiation upon mere oxygen but is formed *reversibly, in a complex electrolytic system*, in which oxygen is associated not only with a determinant (δ) but also with a catalyst (κ)—as the outcome of a series of interactions. I may refer to my article on "Catalysis and Oxidation," in Nature of August 22, 1925, p. 294, where I have discussed the process

The necessary conditions may well prevail in the upper atmosphere—they must, in fact, if it be formed at all. Let it be assumed then, that the condition be such, that the change of oxygen into ozone is not greatly encouraged—that it is difficult, on the whole, a large quantity being produced, during daylight, only because of the intensity of the solar effect. Then it equally follows, that the reverse action will take place only slowly and the accumulated energy be let down (electrically) only slowly, so covering the period of darkness, perhaps

It may be dangerous for the mere chemist to put foot down where the angels tread but lightly: still, these are matters to which we have paid some attention and our intervention may not be altogether foolish—the more if it lead some day to better appreciation of the philosophy of dirt, at present unnoticed by the physicist.

Henry E. Armstrong.

Weather Prediction from Observation of Cloudlets.

I WAS greatly interested in Mr. C D. Stewart's letter (NATURE, February 20, p. 270) which expresses my meaning exactly. But I do not know why he should think I regard "as a general method of prediction one which is applicable only in particular conditions, namely, those of showery uncertain weather, and, it may be, in particular localities; and also, to some extent, to the lack of precise definition of the type of cloud to be observed"—*i.e* "the smallest and thinnest fragment of cloud that can be clearly isolated." Captain Cave mentioned some exceptions, and I others. Before the rains in India, I have often seen big clouds form and then dissolve without dropping moisture. I wrote "only for the man who, perhaps knowing nothing about scientific meteorology, desires to ascertain for himself the kind of weather he is likely to experience during the next few hours." Such a one is not likely to examine the sky when it has settled to be wet or fair. Nevertheless, even during a downpour, if he is able to isolate a little dark cloudlet under the grey pall and see it dissolve, he may, even then, predict the early probability of finer weather with fair safety. Not long ago I arranged a game of golf under such conditions. I also wrote, "The nearer the cloudlet (the lower it is) the more closely do the conditions in which it floats approximate to those on the ground, and the more easily may it be observed; and, therefore, the more confident may be the prediction." Of course, therefore, I referred to 'doubtful conditions' and to the 'scud' which then occurs. My eyes, at any rate, cannot make sure of cloudlets very high in the sky, for, because of the distance, what seem to be cloudlets may be considerable clouds. Moreover, these high clouds are so remote, and the conditions in which they float so unlike those in which I stand, that observation of them can be of little utility for weather prediction. On the other hand, observation of the fact that the sky is clear for all the distance up to them gives me an indication of the continuance of fine weather. G. ARCHDALL REID.

March 9.

Ancient Coins from Pondoland.

IN Prof. Raymond Dart's article in NATURE, March 21, 1925, p. 425, reference is made to a find of ancient coins which Prof. Dart states was made in Pondoland by Mr Cook about fifty years ago (p. 427).

At considerable trouble I have traced these coins, and find that there are several very peculiar circumstances regarding them, which I consider throw a completely new light on the whole question.

The coins fall into three distinct groups:

(1) Ptolemaic.
(2) Late Roman.
(3) Byzantine.

Groups (1) and (2) have been accurately described by Prof. Dart. Group (3) consists of two much-defaced coins—a small copper of Constantine II. and a large copper of John I. Now, since this last is the latest coin in the find, and it cannot be given an earlier date than A.D. 969, and since it is so worn that the obverse is completely obliterated, I suggest that the earliest possible date for the burial of the horde would be about a century later, say A.D. 1070, by which date the Arabs were established at Sofala and were probably trading as far south as Inhambane.

Roman coins still, I believe, pass in the Peninsula, and it is quite possible that all the pieces in the find were imported by Arabs.

One most striking feature about the whole thing is the amount of wear shown by the different groups. The Ptolemaic coins are in fair condition, many of the late Roman group are almost in mint state, though others are more or less worn. The Byzantine coins, on the other hand, are so worn that I had considerable difficulty in identifying them. But when it is born in mind that the horde covers from first to last a period of more than twelve and a half centuries, one ceases to be surprised at anything.

J. F SCHOFIELD.

P.O., Durban, February 16.

Uncertainty.

MY exuberant friend Prof Armstrong (NATURE, Feb. 6, p. 195) seems uncertain about many things for which there is good evidence, and to glory in his uncertainty; but there is no merit in uncertainty in itself: it is just as much a sign of crankiness to reject good evidence as it is to accept bad. His attitude prevents his own enjoyment of the great discoveries of the present generation, because they do not dance to the *drone* of his water bagpipe—a serviceable instrument but in danger of becoming a fetish I can only suppose that in his educational policy he has so long refrained from dogmatic instruction, and so persistently advocated other methods as more truly educative, that now he can scarcely recognise a true doctrine when he encounters it

Yet the object of science is truth, not hesitating ignorance; and though caution is admirable it may degenerate into obscurantism Prof. Armstrong would probably have been on the side of the orthodox in the days of Galileo, and might now justify himself by relativity; but progress and truth were on the side of Galileo nevertheless, however crude his formula. A pioneer is usually ahead of orthodoxy.

In his letter, Prof Armstrong virtually asks me to withdraw from the Royal Society because I have gradually reached complete conviction on a subject of age-long debate and uncertainty, and have said so while as yet the majority of Fellows still doubt. I can promise that when such a request is made officially I will resign promptly without giving trouble; but I will not refrain from stating what I firmly conceive to be the truth, as demonstrated by clear and repeated evidence, whenever such statement seems called for If I had any uncertainty about it I would say so, but it is madness to be false to truth—no matter what the penalty may be OLIVER LODGE.

Italy, February 10.

The Constitution of Glauconite.

IN a recent paper (*Rec. Geol Surv India*, 1925, vol. 58, pp. 330-337) Dr. L. L Fermor proposes for glauconite a formula analogous with that already given by Clarke, which I had regarded as inadmissible (*Min. Mag.* 1922, vol. 19, pp 330-333). Dr. Fermor's conclusion is based on the fact that the mean of the glauconite analyses agrees with this formula. But, as he himself shows, the composition varies widely. Indeed, it would be equally logical to derive a rational formula from the mean of the published analyses of plagioclase. Dr. Fermor concludes: "It must be pointed out that . . . the formulæ given are based on averages, and that many of the individual analyses depart considerably from these formulæ." It was exactly for this reason that I felt compelled to reject the formulæ in question in favour of one which agrees almost perfectly with nine out of the twelve analyses available for this rather obscure mineral A F. HALLIMOND

The Electrical State of the Upper Atmosphere.[1]

By Prof. S. CHAPMAN, F.R.S.

DIRECT simultaneous measures of temperature and pressure up to 25 kilometres, by sounding balloons, give complete information as to the variation of pressure, density, and temperature over this range. The temperature falls in the first 10 kilometres from 285° absolute to 220°, and then remains constant up to 25 or 30 kilometres. The temperature above this height was a subject merely for speculation until Lindemann and Dobson published their theory and discussion of meteors. They concluded that the temperature remains at 220° up to 50 or 60 kilometres, after which it rises (perhaps rather rapidly) to about 300°, which is its value up to about 140 kilometres; thus at this height the air is warmer than near the ground. This rise of temperature is inferred from the estimated densities of the air between 60 and 150 kilometres, the density at 100 km. being more than ten times as great as it would be if the temperature had remained at 220°. Higher up the difference between the estimated density and that calculated on the latter assumption is still greater. The mean free molecular path, calculated on the assumption that the air is mainly nitrogen over this range, increases from about 1 cm. at 90 km. to about 10 cm. at 130 km.

Above this level, even if the temperature were fully known, the pressure and density could not be inferred without a knowledge of the composition, as to which, at present, there is much uncertainty. In the lowest 10 km. the air is thoroughly mixed by winds, but at some height H in the stratosphere diffusive separation may begin, the heavier constituents settling out so that the proportion of the lighter constituents steadily increases upwards. Up to about 100 km. the pressure and density do not depend much on H, but the composition is largely affected by it: $H = 20$ km. and $H = 50$ km. would give very different results. If we take $H = 20$ km. as a likely value, nitrogen is still the main constituent at 100 km., its molecules being about fifty times as numerous as those of oxygen and helium. Above 150 km. there will be very little oxygen, and such lighter gases as are present (possibly helium and hydrogen) should be the main constituents.

The question of the composition at 90 km. or 100 km. is of interest in connexion with the auroral spectrum. The conditions there, in any case, are by no means those of a large excess of helium, as supposed by McLennan and Shrum in their discussion of the auroral spectrum. The auroral spectrum shows that nitrogen and oxygen (accepting McLennan and Shrum's identification of the green auroral line) are present at auroral heights. At the lower auroral levels this is quite in accordance with expectation, but auroræ are also said to appear at heights of 500 km. The evidence for this, given by Störmer and Vegard, seems quite satisfactory. The presence of nitrogen and oxygen at such levels seems explicable only on the assumption that the atmosphere is partly supported at great heights by electrical forces, such as were discussed by Atkinson in his criticism of Vegard's theory of the aurora. If such electrical forces operate, either permanently or merely temporarily when auroræ occur, they may have the effect of allowing the lighter gases, hydrogen and helium, to escape altogether: a suggestion which would, if substantiated, explain the rather remarkable absence of hydrogen and helium lines from the auroral spectrum.

Another matter of interest concerning the upper atmosphere is the highly conducting layer, the existence of which is indicated by the diurnal magnetic variation, according to the theory of Balfour Stewart and Schuster. The conductivity of the layer must be of the order 3×10^{-6}, which is so great as to be difficult to explain. But recently Appleton and Barnett have assigned 10^5 as a lower limit to the number of electrons per c.c. at the level, about 80 km. high, at which wireless waves are reflected at night. From this it appears that the specific conductivity must be 10^{-14} c.g.s. units at this height; a layer having this specific conductivity would require to be 3000 km. thick to account for the total conductivity 3×10^{-6}. This excessive thickness can be reduced to a more reasonable figure, however, if the ionisation by day is several times as great as by night (as the diurnal magnetic variations themselves indicate), and if allowance is made for the increase in the mean free path above 100 km. The downward extension of the conducting layer, by day, into regions where the mean free path is less than at 100 km., may not add very much to the total conductivity. There seems no longer, however, any insuperable difficulty in supposing the thickness of the conducting layer to be of the order of 200 or 300 km., without assuming an excessive specific conductivity.

By Sir HENRY JACKSON, G.C.B., F.R.S.

Radio communications have never been noted for their consistency. At first this was attributed to atmospheric disturbances and to the low energy emitted, with reception by unreliable apparatus, but when the power radiated was greatly increased and modern appliances of great sensitivity and constancy were brought into daily use, it was still found that the intensity of the received signals from any station at long distances was variable at times, though it was seldom if ever that signals were entirely lost at the stations designed to receive them. When directional wireless was brought into use, it was found that, in addition to variable strength of signals, great variations were experienced at night in the bearings of the observed stations.

The cause of these variations in intensity and direction have been very systematically investigated during the last five years by the International Union of Scientific Radiotelegraphy and others, and in Great Britain - especially by the Radio Research Board; many hundreds of thousands of observations have been made by skilled observers with suitable and reliable apparatus, and the results have been carefully analysed to try to find a law which could explain the reason of the variations.

The analysis showed plainly that both types of variations were subject to seasonal, diurnal, and 'untraced' effects, and that the altitude of the sun had evidently a great effect on them, but nothing more definite than this was obtained. However, in considering the effects of electromagnetic waves of radio frequency on a wireless receiver, it was deduced that the causes of variation in signal strength and direction could all be accounted for if two or more waves from the same source and of the same frequency reached the receiver simultaneously but at different phases of their oscillations, and for some directional variations, if one of them was polarised in a different plane from the others.

---

[1] Contributions to a discussion at the Royal Society on March 4.

When shorter waves than those employed (until about four years ago) came into general use for broadcasting and also for communications, another variation came prominently to notice; namely, the rapid variations in signal strength called 'fading,' though probably this is only an exaggeration of the first-mentioned effect; and also the fact that although signals may be received at short and also at long distances, there are intermediate zones in which no signals on the wave-length in use can be received at all, or only very occasionally. The Kennelly-Heaviside layer theory had not been lost sight of in the investigations already referred to, and the most recent theories on this were studied and experiments carried out to try if deflexions and conduction by some such agency as this layer could be measured. This has been successfully accomplished by several observers using different methods, and the collective results they have obtained, and independently published, I think, go far towards establishing the validity of the idea. Before a decision can be given, however, it is necessary to know what this deflecting layer must be able to do to meet the calls that are now being made upon it to account for all the varying results that are now observed in radio communications which cannot be attributed to locality, to the apparatus in use, or to the personnel operating it. I will briefly give some typical examples of these, with short waves; those with long waves and directional apparatus have been well known for a long time.

The quantitative effect of the earth's attenuation of moderate and long wave-lengths passing over its surface is not accurately known, but it varies as some power of their length. For high power and long wave stations, such as Rugby, Nauen, and others of this type, it seems possible that this effect is small, and the wave may cover the whole of the earth's surface, and to a lesser extent with shorter waves with less radiated energy; the layer in this case would act principally as a deflector of the waves downwards. But in the case of the very short waves, say less than 50 metres in length, experiments show they are rapidly attenuated by the earth, and not received directly at any great distance from the transmitter.

With Admiralty permission, I will quote a very recent example showing this, namely, with a wave of 12 metres in trials now being carried out under carefully organised conditions and supervision. A ship starting on a long voyage transmitted this wave according to programme every 4 hours for 12 minutes. The signals were regularly received with diminishing clarity up to 100 miles of one of the shore stations, then lost until the ship was 1100 miles off, when they were again received for some days intermittently, and again at about 3500 to 4000 miles, lost again, and then received again with perfect clarity at 6000 miles.

Now this is a case in which the phase difference I previously mentioned cannot well have been the cause, for the ship on its passage either directly or obliquely away from the receiving station, would pass through a wave-length and any of its various phases in about 2 seconds, and in the 12-minute period of transmission would have every chance of changing any phase difference between two waves arriving at different angles.

The small loss (if any) of signal strength at 6000 miles is very noticeable, and from personal observations on four other wave-lengths from this ship, emitted every 4 hours according to programme, I have been able to compare their strength and behaviour with others of the same wave-length emitted by two other Admiralty shore stations similarly equipped, at distances of 90 and 1100 miles respectively The three stations send consecutively, the ship coming in between the other two, the shore stations. The signals from the nearest station are, on the average, decidedly weaker than those from that at 1100 miles. Those from the ship vary, sometimes being very weak, at other times very strong, but at the extreme distance reached, 6500 miles, they were noticeably weaker than when under 5000 miles, at which distance I have received them without Æ or E. Fading of these signals is also noticed, during both day and night, from all three stations, but is more irregular and frequent from the ship at great distances than from the other two (30 per cent. from ship, 22 per cent. from shore stations: 300 observations); but generally, when one of the stations fades, the others do as well. Reception seems better from all three stations when they are transmitting in darkness than in daylight, especially the one at 90 miles on the longest of the wave-lengths. Occasionally double fading is noticeable, that is, a short period of small amplitude, superposed on one of considerable period with large amplitude, *e.g.* 10 seconds and 2 minutes, with amplitudes of 2 to 4, and 0 to 6 in the usual scale of telephone intensities.

At other times, from the ship at long distances, the dots if made fast disappear or are very faint, as if it took an appreciable time to build up sufficient intensity to start the signal on its way. Occasionally long dashes from the ship at long distances are distorted into an audible wave of varying pitch and intensity. Communication on two of these short waves seems to be reliable during some part of the day to the extreme distance the ship reached.

With a longer wave (nearing 100 metres), signals were maintained at night up to 1000 miles, then lost and only received twice in the remainder of the voyage though transmitted 6 times daily.

These results indicate that the layer must exercise but little attenuation on short waves, which show little loss of energy in their passage along it, but that it appears to deflect down some wave-lengths at various places, and others possibly at all points over the earth, and that two or more waves must sometimes reach the receiver in varying phases to account for the extraordinary fading effects that are so often noticed with them.

Is a layer that will fulfil all these functions a physical possibility, is the question which requires an answer; *if not*, what is the cause of these variations?

By Dr. W. H. Eccles, F.R.S.

Preceding speakers having marshalled the available evidence for the Heaviside layer, it may be most useful for me, while agreeing broadly with the conclusions drawn from that evidence, to refer to some other points of view and other agencies. For example, in connexion with wireless phenomena at short distances from the transmitting station, the diminution of the density of the air with increase of height, which causes the lower atmosphere to act as a prism with its base on the ground, taken together with diffraction, must be remembered. Consider a source from which electric waves of length 20 metres, 600 metres, and 20,000 metres are being simultaneously emitted, and consider especially the rays emitted horizontally. Up to distances of 100 kilometres, all these waves can be detected by an ordinary aerial—beyond that distance the 20-metre waves vanish but the others remain perceptible. This, I suggest, indicates diffraction of the longer waves, as is supported by the fact that an aerial on a high mast or hill can detect short waves passing overhead like the beam of a searchlight. I want to suggest also that variations of signal strength at these short distances may be due to variations in or movements of the lower atmosphere. (The well-known vertical oscillations of pilot balloons at a height of 10 kilometres suggest movements of the air.)

Beyond 100 kilometres, in daylight, the 20-metre signals are completely lost, the others are continuously perceptible. It has been found (*e.g.* by Hollingworth) that after falling off with distance, the long wave signals increase up to a distance of 400 kilometres. Here it seems that the ionised atmosphere is aiding diffraction and the prismatic action. At 700 kilometres the lost 20-metre signals reappear, though the tangent plane through the source passes 100 kilometres above. This suggests that the horizontal rays from the source have followed a trajectory perhaps only 30 kilometres in height at its apex and now graze the ground again. Rays starting with an upward angle from the source would, on this view, descend to earth at greater distances and perhaps at grazing incidence. These possibilities have caused me to remain unconvinced by Prof. Appleton's use of the 'skip' of short waves to deduce the maximum electron density at a sharply defined Heaviside surface nearly 100 kilometres high. This possible explanation by the aid of non-intersecting and gradually bending trajectories of varying height demands considerable thickness in the Heaviside layer. It is perhaps in disaccord with Sir Joseph Larmor's recent review of an old theory; for he appears to deny the possibility of bending in the lower atmosphere and also supports the 'whispering gallery' view, which assumes the formation of a thin caustic layer of radiation in the sky.

The preceding remarks refer to daytime propagation. At night the 20-metre waves make a larger skip, say 4000 miles, and are picked up at all distances beyond; the 600-metre waves are picked up at all distances to 5000 miles, and the 20,000-metre waves go everywhere. Measurements are available on the medium wavelengths and show that in the great fluctuations of strength beyond 2000 miles, the maximum may exceed the strength calculated for a perfectly conducting flat earth with a non-absorbing atmosphere. This seems one of the best proofs of the existence of the Heaviside layer, for otherwise we must believe that the earth is flat.

The Glaciers of Savoy.

An important and unusually interesting report, of more than two hundred pages, on the glaciers of Savoy, especially those of the Mont Blanc "massif," the Tarantaise Alps, and those of Haut Maurienne, has been recently issued by the Ministère de l'Agriculture, Département (Direction Générale) des Eaux et Forêts. It is entitled "Études glaciologiques," and represents most valuable results, from the beginning of the century down to the year 1920, obtained by a special "Commission glaciaire de Savoie," composed of high officers of the Département des Eaux et Forêts, aided by specially appointed geologists, geodesy experts, M. Tairraz, the well-known Alpine photographer of Chamonix, and the late M. Joseph Vallot of the Mont Blanc observatory. In spite of the unavoidable reduction of the staff during the War, several members indeed being among the fatal casualties, the work was continued throughout the terrible four years 1914–1918.

The results achieved consist in annual, and in some important cases monthly, measurements of the lengths of the glaciers, determinations of their relative movements at the sides, snouts, upper surfaces, beds, and various parts of their width, estimations of their depths, total volumes, amounts of water they discharge at their lower ends, their gain by snowfalls, and their loss by solar fusion. In addition, a careful record has been compiled of all catastrophic occurrences, such as exceptional avalanches, bursts of lakes and water pockets, earth-quakes and -tremors which have resulted in avalanches or alterations of beds and configurations; and to render this portion of the report still more interesting, historical data have been added concerning all known happenings of this character since the year 1800.

During the last ten years (1910–1920) of the period dealt with, the glaciers on the Savoy side of the chain of Mont Blanc have in general been advancing. For example, the Glacier du Tour reached its minimum length and showed a tendency to grow in 1909, and although there was a slight set-back in 1910 due to special solar activity, in 1911 a distinct move forwards was made, and has continued without interruption up to the end of the report period, 1920. The progressive movement was only communicated to the Argentière glacier four years later, in 1913, as regards maximum length, but even from 1911 there was a growth of several metres a year on the right flank of the snout, until the total length became at last affected in 1913, and the elongation became more and more marked until in 1920 the glacier end moved forwards 40 metres.

The Mer de Glace was difficult to investigate, as its end had been hidden, by its retrogression, in an inaccessible ravine. But from such observations as could be got of the snout, and especially from those on the glacier proper above the Montanvert, it is clear that there has been a forward movement occurring, ever since 1916 with certainty, and probably from 1914. From further observations of the higher portions known as the Glacier du Géant, and of its tributaries, the Glaciers de Leschaux and Talèfre, it is shown that there has been a very considerable increase in the bulk of the glacier, an augmentation of thickness having been observed ever since 1913.

The Glacier des Bossons, the central glacier of Mont Blanc itself, offers the most interesting results, for owing to the snout being so readily accessible by the exceptional advance of the glacier on to the very meadows of the valley of Chamonix, it has been found possible since March 1917 to obtain monthly records of progress. They show that the glacier does not advance *en bloc*, but with a waddling motion, sometimes one side, sometimes the other, and sometimes the middle of the front, moving most during the month, like a heavy man walking in such a manner as to advance each shoulder alternately. Moreover, in summer the left of the front moved, on the whole, the more rapidly, and in spring and winter the right; the former is due to greater melting of the ice on the side showing least motion, and the latter to the form of the glacier bed, the line of maximum movement of a sinuous glacier being, as is well known, on the convex side of the central line of the glacier, that is, nearer to the concave border. Since the year 1910 the annual march of this glacier has varied from 33 metres during the first year (July 1910–July 1911) to 51 metres in 1917, from which it slowed down to 23 metres in 1920. The advance was greatest in spring, then next in summer, then in winter, and slowest in autumn. The mean values for the four years 1917–1920 were 11 metres in spring, 5·2 metres in summer, 5·1 metres in winter, and 1·7 metres in autumn. In spring there is extra pressure from above, owing to accretions from the névé of the higher snowfields, undiminished by melting, as the spring sun has first to melt the fresh winter snow. But in summer the movement is diminished by real fusion and thereby loss of solid ice, combined with reduced pressure from above, the weight of the winter snow having been removed by melting.

The Glacier de Bionnassay has been advancing since the year 1916 with certainty, and probably since 1914. The last measurements had been in 1913, and between then and 1916 the front of the glacier had advanced 30 metres. It continued at this rate more or less steadily down to the report period 1920.

Thus it is clear that the glaciers of the French Savoy side of the chain of Mont Blanc have all advanced, the amount being accentuated in the cases of the steeper glaciers, Le Tour, Argentière, and Les Bossons. In the more slowly moving cases, the Mer de Glace and the Trélatête glacier, the increase has been chiefly one of bulk and of thickness.

The glaciers of the Tarantaise, and other Savoy Alps, which are much influenced by the Lombardian winds of the valley of the Po, have either advanced to a less amount than those of Mont Blanc, or have retrogressed. The latter, for example, has been the case with the Glacier de la Vache (Source de l'Isère).

Special reference should be made to the particularly interesting determinations of the thickness of certain glaciers. The late M. Joseph Vallot obtained results on the Mer de Glace, at widely different positions in its course, which varied from one hundred to two hundred metres of solid ice; and he came to the conclusion that the latter figure represents the maximum depth. This estimate is almost exactly confirmed by these later measurements and estimations by the Department des Eaux et Forêts, the opinion being that, if not quite accurate, it errs on the low side.

The observations conclude with some remarkable estimates of the volume of additional ice represented by the advance of these glaciers. The Glacier du Tour has increased per annum between 1911 and 1920 by the amount of eight and a half million cubic metres. The glacier of Argentière has increased in volume by one to three million cubic metres per annum of solid ice; and the Mer de Glace has shown a similar amount of swelling, until in 1920 the exceptional heat caused a slight net loss. The Bossons glacier has enlarged by amounts varying from one-sixth to one-half million cubic metres a year. The glaciers of Bionnassay and Trélatête have gained in volume of solid ice between 1912 and 1920 more than five million and seventeen million cubic metres, corresponding to an increase of thickness of the glaciers of seventeen and six metres respectively.

The French Department des Eaux et Forêts is to be most sincerely congratulated on this magnificent piece of accurate work. It is to be hoped that the observations have been carried on beyond the year 1920 in an equally satisfactory manner, and that they will be continued. It would appear that this is being done, for the writer has several times come on the officers of the department at work during his recent summer visits to the Savoy mountains, both Mont Blanc and the Tarantaise Alps, including one paid this last summer, and has had personal experience of the admirable way in which the measurements are being carried out.

A. E. H. TUTTON.

Obituary.

SIR PHILIP WATTS, K.C.B., F.R.S.

SIR PHILIP WATTS, who died on March 15, was born in May 1846, being thus nearly eighty years of age when he died. He was educated at the Dockyard School at Portsmouth and the Royal School of Naval Architecture, South Kensington, completing his education in 1870. Until 1885 he spent most of his time at the Admiralty on the Naval Constructor's staff, which afterwards became the Royal Corps of Naval Constructors.

During this time Sir Philip was engaged in the design work of the office which then produced such original designs as the *Inflexible* with 24 in. of armour and four 16-in. 80-ton guns; the *Iris and Mercury*, the first all-steel ship and the fastest then produced; the *Polyphemus*, an armoured ram which was almost submerged; and many other original designs. He assisted Mr. Wm. Froude in the classic observations on the behaviour of the battleship *Devastation*, one of the first of the mastless turret ships in H.M. Navy. He took a leading part in the investigations of the *Inflexible* Committee, which was created as the result of doubts expressed as to the fighting and seaworthy qualities of that ship. He designed the rolling chambers of the *Inflexible*, and went to sea in her to observe the effects of the chambers on rolling.

Sir Philip was thus associated with most of the scientific development of naval architecture at the Admiralty between 1870 and 1885, at which date he began his independent career in charge of the design and construction of warships at Armstrong's works on the Tyne, in which position he remained until 1902, when he accepted the position of Director of Naval Construction at the Admiralty. His active career as warship designer extended for well over half a century, and during this time he was associated with a continuous increase in efficiency and battle power of the many ships for the design of which he was the responsible creator. His reputation stands unrivalled for the quantity and quality of his work. Of the warships which he designed and built when at Armstrongs, the cruisers were the fastest and best armed of their day, and the battleships were the most powerful. Nearly all the warship fighting done by the Japanese victorious fleet in 1894 and 1905 was done in Watts's ships.

When Sir Philip went to the Admiralty, two of the King Edward class of eight battleships had been commenced. He produced designs having much greater gun power, and not inferior in other respects, with the view of building a squadron of eight ships much more powerful than the King Edwards, but My Lords decided to complete the inferior ships. This was discouraging to the man who wanted to give our ships as much gun power as possible. On the appointment of Admiral Fisher as First Sea Lord, however, Sir Philip's chance came, and he had hard work to give Fisher all the guns he wanted. The all-big-gun ship was wanted. Its adoption was approved by the Committee on Warship Design appointed to consider the question, and the Director of Naval Construction produced the complete designs for the Dreadnought type approved by that Committee. Thus, by the energy of Fisher and the skill of Watts, was begun the series of Dreadnoughts and super-Dreadnoughts of which the Grand Fleet was largely composed—which, to adapt the phrase of Mahan, stood between the Germans and the conquest of the world. Watts could not have attained and maintained such a position without a very full knowledge of all that pertains to warships, not only the structure of the ship but also the principles underlying armour, gun and machinery production, and a full appreciation of the strategy and tactics of sea warfare and of the life and ambitions of the great sailors of his time.

Watts was one of the earliest graduates of that school of naval architecture which began in the 'sixties, developed in the 'seventies into the Royal Naval College at Greenwich, and has continued ever since to turn out men of high attainments to fill not only that able Corps of Naval Constructors (over which Sir Philip presided) but also the Royal Naval Engineers, who have so ably assisted in the enormous developments of marine engines which have taken place since the school was founded. Sir Philip, like his predecessors and successors, saw to it that this source of supply of naval constructors and engineers was fully maintained. He assisted in the creation of the professional chairs and the schools of naval architecture in Glasgow, Durham, and Liverpool, from which so many naval architects and marine engineers have graduated and have found scope for their abilities in the ship and engine works of Great Britain.

Sir Philip's great scientific attainments and his practical skill in applying his knowledge were recognised by the Royal Society, of which he was a fellow and vice-president, and by the universities which conferred on him LL.D. and D.Sc. degrees. It was, however, in the Institution of Naval Architects that his work was best known. He contributed many papers of high value and always took an active part on the Council of the Institution. He frequently presided at the council and general meetings, being for many years the senior vice-president. When at Armstrong's he was an enthusiastic territorial gunner and had the rank of Colonel. He was not a great talker in public or private, but all who had the privilege of his friendship will remember him as a generous and genial man with sound common-sense and wide scientific interests, which, combined with a gifted imagination and great courage, enabled him to carry through his important work successfully.

PROF. ERNST EHLERS.

PROF. ERNST EHLERS was born on November 11, 1835, in Lüneburg in the kingdom of Hanover, where his early education, carefully supervised by his father, who was a merchant, was received, and where the ancient buildings and historical surroundings doubtless had an influence on his sensitive mind. His training consisted of a good knowledge of classics, of history, mathematics, French, and chemistry, whilst his natural bent found a congenial field in faunistic works. He then (1857) proceeded southward to the University of Göttingen, where he energetically studied medicine and natural science, two subjects so intimately related, as all history shows, that the efforts of the late Scottish Universities Commission to separate them are vain. Amongst the professors there, none interested him more than W. Keferstein, R. Wagner, and Bödeker. There were comparatively few zoologists of the period who, like Ehlers, entered on their later studies with broad views and a thorough acquaintance with both vertebrate and invertebrate anatomy. It is true in his early days he had not the advantage of a life on the sea-coast and of familiarising himself with marine life from Protozoa to mammals; but he balanced this by his able researches on structure and by his skilful pencil, so that amongst the distinguished zoologists of the period he stands prominently forward.

Ehlers' abilities and natural bent were soon observed by Keferstein, who took the young naturalist with him to Naples and Messina, introducing him to the rich marine fauna there, the joint authors producing a memoir on the Siphonophores. In 1861 he received the degree of M.D. at Göttingen, his thesis being the "Anatomy of *Priapulus caudatus*," the material for which he had obtained from the well-known Japetus Steenstrup of Copenhagen. The same year he was appointed prosector to the Anatomical Institute of Göttingen, and two years later a private tutor in zoology and comparative anatomy.

His association with the leading zoologists of Germany and Austria led Ehlers to select the fine field for work in the group of the polychæts, so that in an expedition (May–August) to Fiume in the Adriatic, he worked his nets and searched the beach specially for those forms, to the study of which he applied modern methods. A better seaman than his distinguished countryman, Albert Kölliker (who was helpless in the surging English Channel), he was enabled to make full use of his opportunities in these waters. Ehlers began systematic work in the polychæts at a time when—by the labours of Grube, De Quatrefages, Johnston, W. Baird, Agassiz, and others, they were attracting attention everywhere—no less from their beautiful coloration than from their wonderful structure and life-histories; and he resolutely, from first to last, adhered to their elucidation both as regards European and more distant seas.

Ehlers' two early volumes "Die Borstenwürmer," each with about a dozen quarto plates, were by their careful systematic treatment sufficient to lay the foundation of a solid reputation, and they attracted much attention in Great Britain, so that when the results of the *Lightning* and *Porcupine* Expeditions were dealt with, Ehlers was assigned the polychæts dredged below 500 fathoms, and they formed a valuable contribution in the *Zeit. f. w. Zool.* for 1871. It would not be possible to deal minutely with his great labours —even in the polychæts—which added many new genera and species to the group, and brought to light new features in their structure and life-history; for his observations ranged from the fossil forms in the Solenhofen slate to the most recent deep-sea expeditions of his own country and of the Americans, and extended from the Atlantic to the shores of New Zealand, as well as ranging from pole to pole. Some of his memoirs formed quarto volumes of considerable size, and most were finely illustrated, sometimes in colour, by his skilled artist, O. Peters. He was *facile princeps* in the Department in his day, yet he bore himself with perfect modesty and was ever ready to help others. Nor were his labours confined to the polychæts. The gephyreans, tunicates, and Bryozoa on one hand, *Lepidosiren*, the Porbeagle shark, the *chorda dorsalis*, and the anatomy of Manis on the other hand, each became the subject of one or more memoirs—thus demonstrating the versatility of his vigorous mind and his indomitable powers of work.

Ehlers' connexion with the *Zeitschrift für wissenschaftliche Zoologie*, the leading journal of zoology in his country, dates from 1875, when the veterans Von Siebold and Kolliker added him to the staff, and as the seniors passed away he became sole editor —until lately. His entrance into this work was signalised by an increase in the size of the journal, and indeed it occasionally doubled its bulk both as regards memoirs and plates. Yet he did not desert the Gottingen publications, in which many of his contributions appeared afterwards. The name of Ehlers is honoured wherever the science of zoology is known, and he truly wore the sword out instead of letting it rust out, for he held office until he had almost reached his ninety-first year, when release from his labours reached him. His unselfish devotion to zoology moved his friends, at home and abroad, in 1905 to prepare a *Festschrift* in his honour, and the memoirs were published in the *Zeitschrift f. w. Zool.*, and are a sufficient testimony to his fame. Moreover, a second *Festschrift* was in process of arrangement in 1914, but the outbreak of the War put an end to the project. Ehlers thus forms a conspicuous example to all the younger zoologists for his unswerving devotion to his early subjects, his wide and accurate knowledge, his skill with his pencil, and for his arduous and unceasing academic labours. Of him Gottingen may well be proud.

W. C. M'INTOSH.

DR. C. V. PIPER.

BY the death, on February 11, of Dr. Charles Vancouver Piper, the United States Department of Agriculture loses a worker of wide reputation and long service. At the time of his death he was in charge of the Office of Forage Crop Investigations, and through his efforts many plants and grasses of much value to American agriculture have been introduced and established in the United States. He was best known to the general public through his work in developing the creeping bent grass for use on golf greens. In 1919 he discovered a particularly useful variety, propagated it by vegetative means, and distributed it throughout the northern section of the United States, where it is now found growing on thousands of golf greens. Dr. Piper was keenly interested in the game, and utilised his knowledge to the full to improve conditions for players everywhere.

Dr. Piper's contributions to the forage and grass industry of practical agriculture were numerous, perhaps the best known being the introduction and establishment of the Sudan grass (from Africa), which is now a very valuable hay and pasture grass in the States. More than one hundred books and papers on agriculture and allied subjects stand to his credit, and he was consulting agricultural editor for the McGraw-Hill Book Company. In his search for new forage plants he travelled widely, spending much time in Japan, China, India, Java, Egypt, the Philippines and Alaska.

Dr. Piper was born at Victoria, B.C., in 1867, took his M.S. degree at Washington in 1892, and remained there as professor of botany until 1903, when he received his appointment to the Agricultural Department at Washington, D.C. He was associated with many societies, serving in 1908–9 as president of the Botanical Society of Washington, and in 1913–14 of the American Society of Agronomy.

WE regret to announce the following deaths:

Dr. William Tufts Brigham, director-emeritus of the Bernice Pauahi Bishop Museum, Honolulu, known for his work on Hawaiian customs, on January 29, aged eighty-four years.

Sir Bradford Leslie, known for his work on bridge design and construction, who studied his profession under Brunel, on March 21, aged ninety-four years.

Dr. William E. Safford, economic botanist for the United States Department of Agriculture, who devoted himself to the study of the plants and plant products of the American aborigines and of the early history of cultivated plants generally, on January 10, aged sixty-six years.

Prof. Sutherland Simpson, since 1908 professor of physiology in Cornell University, Ithaca, and formerly lecturer in experimental physiology in the University of Edinburgh, the author of numerous papers on the nervous system, body temperature, and secretory glands, aged sixty-three years.

News and Views.

THE controversy which has arisen through the Admiralty Order of November 1925, which adversely affected the status of engineer officers in the Royal Navy, has been carried a step further by the publication of the Memorandum drawn up by the Joint Committee of the Engineering Institutions. We referred to the deputation which waited upon the First Lord, the Right Hon. W. C. Bridgeman, M.P., in our article "The Status of the Naval Engineer" in our issue of February 6, p. 185. Mr. Bridgeman's written reply is evidence of the conservatism which seems to pervade the Admiralty, and the reply of the Committee states that "they view his statements with grave concern as a symptom of the attitude of mind prevailing at the Admiralty." The Committee adds that it is proposed to take steps both in the Press and in Parliament to make its views known to the public. It certainly seems an anachronism to-day, when the engineering branch is of such vital importance, that the Engineer-in-Chief has not a seat on the Board, even when matters affecting his department are discussed.

THERE is an aspect of the question of the status of the engineering personnel of the Royal Navy to which attention should be directed. The Admiralty has published particulars regarding the forthcoming examination for special entry cadets, eight of whom will be required for the executive 'category' and twenty-five for the engineer 'category' of officers. On previous occasions when the engineering personnel question was in the limelight, there was a serious falling off in the number of candidates. We hope that this will not be the case now. The Navy never stood in greater need of the pick of our schools than to-day, and though parents and guardians may view with distrust the policy of the present Board of Admiralty, we believe that, in spite of the temporary set back it is suffering, the engineering branch of the Royal Navy has an ever-increasing national duty to fulfil.

AT the invitation of the Prime Minister of the Commonwealth of Australia, Sir Frank Heath, head of the Department of Scientific and Industrial Research in Great Britain, has for some time been inquiring into those problems presented by Australian primary and secondary industries which call for thorough scientific investigation. His object has been two-fold: to discover directions in which work in Australia may be linked with that now being carried on in Britain, and to advise the Government as to the most effective way of reorganising the Commonwealth Institute of Science and Industry. In his several public speeches on the subject of industrial research, Sir Frank has emphasised three points. The first is the present lack in Australia of thoroughly trained investigators, which is accentuated by the slight opportunity afforded to university science teachers for extensive research work; the second is the urgent need for thorough understanding and co-operation between Commonwealth and State governments; the third is the necessity for concentrating at first upon problems of the primary industries. He has also emphasised the fact that the magnitude of the Australian continent greatly increases the price which Australia must be prepared to pay for adequate scientific investigation of her numerous problems. The distance factor, indeed, makes the general Australian problem of organisation very different from, and in some ways much more difficult than, that which is being met in England by the Department which Sir Frank Heath superintends.

THE Friday evening discourse at the Royal Institution on March 19 was entitled "Chips from a Sculptor's Studio," and was given by Mr. John Tweed, who designed the equestrian statue of Sir George White in Portland Place. As a practical sculptor Mr. Tweed told how a statue is made. The size and material are chosen to suit the surroundings—bronze being the most suitable if the statue is to be exposed to the weather. Expression is first conveyed to the clay sketch. The material is on a skeleton form. The process the Egyptians first used was the plaster cast and then the finished work in the material chosen The thinness of the bronzes used by the earlier artists cannot be attained at the present time, and there is need for science to discover a more suitable bronze for statuary. In sculpture proper, carving in marble is done with a specially designed instrument by a carver, and then the sculptor completes the work. The material naturally used by the Greeks was marble. The artist gets his inspiration by studying Nature, that he may show the aspect of Nature in his work. Photographs of examples of Egyptian and Grecian sculpture in various materials were shown.

ACCORDING to a dispatch from the *Times* correspondent at Delhi, the Assembly on March 18 rejected the proposal of the Government of India to vote a sum of 375,000*l*. to the Institution of Archæological Research Fund. The proposal was strongly opposed by several Hindu members, who put forward the claims of university and medical education, and by English unofficial members, who argued that the establishment of an equivalent British Museum fund would remove archæological investigation from the annual criticism of the legislature. As no provision had been made in the Budget for archæological research in the expectation that the proposal would be accepted, it was agreed that a supplementary demand for 15,375*l*. should be submitted on the following day. The decision of the Assembly will cause profound disappointment to those who appreciate the importance of the work which is now being carried out by the Archæological Department and are acquainted with present conditions in India. It had been anticipated with some confidence that this vote would place archæological studies in India on a sound basis and would enable a scheme of research covering a period of years to be framed, affording an opportunity of training workers in the principles and methods of archæological investigation—a matter of supreme moment now that the discovery of a centre of prehistoric culture in the Indus Valley is likely to give investigations in this area an importance in the history of civilisation at present incalculable. Sir John Marshall in a recent speech, in referring to the discoveries at Mohenjo Daro and Harappa, spoke of the possibility of inviting co-operation from outside; but whatever form such co-operation might take, there should be some assurance that India itself will be prepared in the main to accept responsibility for the continuance of this important work by competent and fully trained archæologists.

THE forthcoming polar flight of Captain R. Amundsen was the subject of a recent lecture in Rome by Col. U. Nobile, who will command the dirigible airship of the expedition. The lecture is now published in an illustrated pamphlet containing maps of the route From a study of weather conditions in the Arctic regions, Col. Nobile believes that spring offers the best chance of steady weather and long range of visibility. He thinks that the flight should be made not later than May. The route will be from King's Bay, Spitsbergen, where mooring-posts for the airship are now being prepared, to Point Barrow in Alaska. This route crosses the heart of the unknown area in the Beaufort Sea, and should lead directly across Crocker Land, if that land exists. A problem of some importance is the selection of a route to Spitsbergen from Rome. The alternatives are Rome, London, Pulham, Trondhjem, Spitsbergen; or Rome, Fredericks-haven, Leningrad, Murmansk, Spitsbergen. The second route is 500 miles longer than the first, but offers greater probability of quiet weather conditions, and would appear at present to be the route selected. Col Nobile expresses great confidence in the prospects for a successful flight.

WITH the object of giving the American public a bird's-eye view of the services rendered by the National Bureau of Standards, a special circular has been prepared in which its activities are described in non-technical language It contains 113 pages, 86 illustrations and a plan of Washington showing how the Bureau may be reached. The visitor is supposed to be taken through the various departments in turn, and is told the main purpose of each and how it is attained. In many cases some striking result which has followed from the work done in the department is mentioned, as for example the scientifically designed gas burner which gives an efficiency four times that of the usual burner and will effect a saving of 50,000*l.* per day to the United States; and the standardisation being gradually introduced into industry which will reduce the number of unnecessary sizes and varieties of products. The circular forms an interesting and important document and should remove any misgivings as to the great value of the Bureau as a national investment.

MR. C. LEONARD WOOLLEY'S monthly progress report of excavations in Mesopotamia on the site of the temple of the Moon Goddess at Ur, which appeared in the *Times* of March 16, records several discoveries of exceptional interest. Among these is a small chamber containing three stelæ inscribed with the name of Bur-Sin, apparently a shrine for the cult of the deified founder of the temple—a find unique in Mesopotamian discoveries. There is also a diorite statue of the goddess Bau, patroness of the poultry-yard, in the form of a squat seated figure in an elaborately flounced dress, which is the first female statue of early date to be found in Mesopotamia. An alabaster lunar disc dedicated by a daughter of Sargon of Akkad (2750 B.C) shows in relief a sacrifice to the goddess by a priestess, who may be the princess herself, while a limestone plaque dating from well before 3000 B.C, an excellent example of the early art of the country, carved in relief in two registers, shows sacrificial scenes in which in one case the king, and in the other a priest and priestess, pour libations to the god.

VOL. 69 of the Memoirs and Proceedings of the Manchester Literary and Philosophical Society contains the inaugural Ludwig Mond Lecture delivered in the University of Manchester on October 20, 1924, by Prof. H. B. Dixon. Prof. Dixon traces in an interesting manner the rise of the alkali manufacture and the share which Ludwig Mond had in its development. In partnership with John Brunner, Mond started the Solvay ammonia soda process at Winnington in 1873, and in the face of really imposing difficulties they made the process, which had failed in the hands of previous technical men, a success. Mond's contributions to pure and applied science are recorded, and his generosity in helping research is especially commented upon. Ludwig Mond was an example of a rare combination of keen interest in pure science with great ability in its application to the problems of industry.

SOME account of Russian scientific exploration in Arctic Russia and Novaya Zemlya is given in several recent issues of the *Weekly News Bulletin* of the U.S.S.R Society of Cultural Relations with Foreign Countries. For the past four years an expedition under Prof. Samoilovitch has been at work in Novaya Zemlya, and succeeded last summer in rounding the northern end and exploring the little-known north-east coast, discovering several new gulfs and making minor changes in the charts. A site has been chosen for a radio station, for meteorological purposes, at the northern end of the north island. Another expedition under Prof. Suvorov has been exploring the little-known Cheshskaya Gulf of the Kanin Peninsula and examining the fisheries of the coast. Investigations in biology and anthropology have also been conducted in Kolguev and the Kola peninsula, and experiments have been made in several districts of the north in the use of a serum against anthrax in reindeer. All these and other researches are to be continued next summer.

In the National Museum of Wales at Cardiff there are two important collections of British Lepidoptera, the Vivian and the Griffith, which together comprise more than 50,000 specimens. The authorities of the Museum have recently issued a "Guide" (price 6*d.*) to these collections, which directs attention to many interesting and scarce specimens of which no previous record has been published The occurrence and distribution of various Lepidoptera in Wales are also indicated in this pamphlet, while a number of the rarer species are illustrated on two coloured plates. The booklet will prove of interest to collectors and others with respect to unique or very rare specimens contained in the collections, since it gives the localities and other data associated with them. So much is heard respecting the disappearance of rare or local Lepidoptera that it is refreshing to learn from this pamphlet that, at any rate, the white-letter Hairstreak, *Thecla w-album*, appears to be extending its range in so far as Wales is concerned.

The "Report of the Health of the Army for 1923," recently issued, contains details of some interest. Judging by the invaliding rate, the health of the Army was better in 1923 than in the previous two years, but not so good as in the period 1906–13. It is surprising to learn that tonsillitis takes third place, with 5566 cases, as a cause of admission to hospital, malaria with 13,158 cases and venereal diseases with 10,807 cases being first and second respectively. No definite reason could be assigned for this high incidence of tonsillitis. At the head of the list of diseases which cause the greatest amount of invaliding out of the Army comes inflammatory conditions of the middle ear, with 451 cases—nearly half a regiment! The Royal Army Medical College, in addition to courses of instruction and research work, now prepares all the bacterial vaccines and allied substances employed in the Army, which were formerly purchased, at a saving estimated at 12,650*l.* for the year.

Dr. R. E. M. Wheeler, since 1924 Director of the National Museum of Wales, has been appointed Keeper, Secretary, and Accounting Officer of the London Museum, in succession to Mr. F. A H. Oates, who has retired.

Probably no division of biology has so many journals devoted to its various aspects as entomology. A new American periodical, *The Pan-Pacific Entomologist*, a quarterly journal of general entomology, was inaugurated last year. The first volume, consisting of four numbers, has been completed and vol. 2 is now appearing. The journal is published by the Pacific Coast Entomological Society in collaboration with the California Academy of Sciences. Although primarily intended for furthering an interest in the entomology of the coastal region of the Pacific side of America, papers of broader significance are not precluded The annual subscription is 2 dollars for the U.S. and Canada, and 2·25 dollars for elsewhere. Sample copies are obtainable from Mr. F. E. Blaisdell, 1520 Lake Street, San Francisco, California.

Reference has frequently been made in the columns of Nature to the difficulty experienced in central European countries, since the War, in gaining access to outside scientific proceedings and publications. In many of the smaller Continental universities this condition still prevails, and cannot be ameliorated owing to the lack of funds for the purpose. Much valuable assistance could be rendered in this matter, however, if workers in the various branches of science were to make a point of sending reprints of their publications to the leading Continental exponents of the subject concerned. In physics, the need of such an arrangement is particularly acute at the present time, when two "Handbucher" of physics are in preparation. Prof. K. W. F. Kohlrausch has been entrusted with the volume on "Radioactivity" in one of these "Handbücher," and he has written to us suggesting that workers in radioactivity forward to him their publications in this subject, so as to enable him to bring his work completely up-to-date by first-hand reference to original papers. He would be very grateful if the authors of such papers would assist him in this manner, by sending reprints to · I. physikalisches Institut, Technische Hochschule, Graz (Austria).

At the Southampton meeting of the British Association in August last year, a number of papers were read by officials of the Ordnance Survey. These papers are now collected and printed in full in Professional Papers, New Series, No. 10 (H.M S.O., price 9*d.*), and include an admirable general account of the work of the Ordnance Survey by Col. E. M. Jack; a paper on recent productions by Capt J. G. Withycombe, in which announcement is made of a new three-sheet map of Great Britain on a scale of 10 inches to a mile; a paper on archæology and the Ordnance Survey by Mr. O. G S. Crawford; and an account of the present state of the international 1/M map by Maj. M. N. Macleod. The publication gives a useful summary of the present state of the survey and maps of Great Britain.

Messrs. Gurney and Jackson announce the early publication of "A Text Book of Organic Chemistry," by Prof. Julius Schmidt, translated by Dr. H. Gordon Rule; and "A Text Book of Inorganic Chemistry," by Prof. Fritz Ephraim, translated by P. C. L. Thorne.

Catalogue No. 398 of Messrs. Bernard Quaritch, Ltd., 11 Grafton Street, W.1, will appeal to zoologists and geologists, especially if they are interested in rare and choice editions, for it contains particulars of nearly 1800 works, many of which are out-of-print and scarce.

Messrs. H. K. Lewis and Co, Ltd., have recently issued two interesting lists of second-hand books dealing respectively with "Early Scientific Works and Biographies," and "Early Medical Works—Medical History and Biography." Either list, or both, can be obtained free upon application.

Applications are invited for the following appointments, on or before the dates mentioned:—An assistant to carry out research work on miners' electric lamps—The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (April 9). A junior chemist at the Building Research Station, Garston, near Watford, for investigations on the heating and ventilation of buildings—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (April 10). A professor of zoology in the University of Cape Town—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (April 14). A professor of physics in the University of Tasmania, Hobart—The Agent-General for Tasmania, Australia House, Strand, W.C 2 (April 15). A junior scientific officer for work connected with aeronautical instruments at the Royal Aircraft Establishment—The Superintendent, R A.E., South Farnborough, Hants (April 17) (quoting Ref. A. 107) A principal of the Sir John Cass Technical Institute—The Correspondent, Sir John Cass's Foundation, 31 Jewry Street, Aldgate, E.C 3 (April 24). A junior lecturer in mathematics, a lecturer in geography, and a lecturer in geology and palæontology at Bedford College for Women—The Secretary, Bedford College for Women, Regent's Park, N.W 1 (May 8). A professor of natural history in University College, Dundee—The Secretary and Registrar, The University, St. Andrews (May 8). A professor of physics in the University of Dacca, Bengal—The Registrar, University of Dacca, East Bengal, India (June 30). A test assistant for aircraft and instrument test work at the Aeroplane and Armament Experimental Establishment, R.A.F., Martlesham Heath—The Secretary of the Air Ministry, Adastral House, Kingsway, W.C 2 (quoting S. 2/R 461). An assistant lecturer and demonstrator in botany at the South-Eastern Agricultural College, Wye, Kent—The Secretary A pathological laboratory assistant for the Veterinary Department of the Government of Nigeria—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/14292).

Our Astronomical Column.

PENUMBRAL LUNAR ECLIPSES.—The January issue of *L'Astronomie* contains an article by M. Gaetan Blum on this subject. Consideration of these eclipses is necessary to make the theory complete; when they are included there must be one lunar eclipse at every passage of the sun through either node, and there may be two. The almanacs as a rule do not give predictions of penumbral eclipse, but they have done so occasionally by some caprice. Eclipses in which the moon penetrates deeply into the penumbra are quite readily observable, it being obvious that a portion of the moon is dimmed by a smoky veil. There will be an eclipse of this kind on December 19 next, full moon being at $6^h\ 8^m$ A.M., so that it will be visible in Great Britain. The least distance of the moon's limb from the umbra will be less than a minute of arc. The article notes that the phenomenon is rendered more noticeable if the moon's light is weakened by reflection at an unsilvered glass surface.

A very instructive diagram shows all the eclipses of a Saros cycle (1908 to 1926), different symbols being used for each species of eclipse. It brings out clearly both the approximate 4-year cycle of recurrence and the much more exact one in 18 years 11 days.

The same publication contains a photograph of the solar eclipse of January 24, 1925, taken by Prof. Slocum at Middletown, and a diagram showing the exact position of the southern boundary of totality across New York as deduced from the observations made there.

THE JOHANNESBURG 24-INCH REFRACTOR.—This instrument is now in full working order, and is giving satisfaction The outer portion of the lens is less good than the rest, so a slightly diminished aperture is employed

Dr. Van den Bos, of the University of Leyden, is engaged on an exhaustive search for southern double stars with the instrument He has already found more than 180 new pairs, while according to a message which was published in the *Times* some weeks ago, the star β-Tucanæ has been found to consist of three separate pairs, making a splendid sextuple system. This rapid increase of the known southern binary systems calls for a new general catalogue of these objects, which is now in course of preparation at the Union Observatory. It is being printed by a typewriter and will be issued in separate sheets, so that new pages can easily be inserted

It is noted that the planet Pallas appeared on a recent occasion exactly like a close binary star, and was for a time mistaken for one.

THE TEMPERATURE OF SUNSPOTS.—A preliminary paper on this subject by Prof. V. Bjerknes appears in *Comptes rendus*, 182, 48, 1926. The author has contributed largely to the dynamics of meteorology, and his important investigation on the "Dynamics of the Circular Vortex" will be found in *Geofysiske Publikationer*, vol. 2, No. 4, Christiania, 1921. In the present paper the general principles previously established by him are applied to the problem of sunspots, in which the relative coolness is considered by him as an analogous phenomenon to the relatively low temperature in terrestrial cyclones. He postulates a fluid medium possessing a free surface and the properties of a gas with density increasing downwards more rapidly than would result from compression. For a horizontal vortex in such a medium, Prof. Bjerknes develops an expression for the fall in temperature ($\Delta T = T - T_0$) in the central part of the vortex—nat. log $T/T_0 = 2D/H$, where D is the depth of the depression of the free surface, and H is the depth to which vortical motion extends. Applying this formula to a sunspot vortex, given $T = 6000°$, the following depressions of temperatures are given:

$D/H =$	0·001	0·01	0·1	0·2	0·3	0·4	0·5
$\Delta T =$	12°	120°	1100°	2000°	2700°	3300°	3800°

It is found as a corollary that the velocities in corresponding vortices should range from a fraction of a kilometre to 20 km./sec The theory is stated not to be invalidated by the possible absence of a free surface in the sun, so long as there is a rapid change in the densities of the solar gases from photosphere outwards.

It may be added that the temperature of a sunspot at photospheric level is generally considered to be about half that of the photosphere itself. Prof. H. N. Russell, in a "Note on Cooling by Expansion in Sunspots" (*Astrophysical Journal*, 54, 293, 1921), gives as the temperature of the photosphere 6000° C.; of the spot at the same level, 3500° to 4000° C.; at base of the spot vortex, probably 20,000° C. (rough estimate).

Research Items.

STONE IMPLEMENTS FROM NIGERIA.—The Geological Survey of Nigeria has issued as Occasional Paper No. 4 a communication by Mr. H. J. Braunholtz, describing a number of stone implements of palæolithic and neolithic types found in the alluvium of the Bauchi Plateau. Their discovery is a by-product of the tin-mining industry, which necessitates removing and sifting large quantities of alluvial deposit in river valleys. The depth at which they are found varies from a few feet to 30 feet. Unfortunately this affords no criterion of age, and further, the exact location of the finds has not always been recorded. In some cases, however, the depth and situation taken together seem to argue a considerable antiquity such as, *e.g.*, a site "under 20 feet of alluvial and 85 yards from the recent river edge." The implements are, with one possible exception, of local rock and of local manufacture. The palæolithic implements are made of a quartz porphyry, the neolithic of basalt (dolerite). Many of the former are much rolled. Allowing for differences due to the employment of a different material, the palæolithic implements resemble western European types of the Chelles to Le Moustier epochs, but not of the later palæolithic times. While the neolithic types are widely distributed in Nigeria, the Bauchi Plateau is the only site in the provinces up to the present on which palæolithic implements have been found The absence of late palæolithic forms suggests either an isolation of Nigeria from ultra-Saharan Africa at this period, or lack of stone suitable for finer flaking, or, possibly, a more recent origin than their typological affinities in North Africa and Europe.

PAINTED POTTERY FROM MESOPOTAMIA.—Mr. W. F. Albright, of the American School of Oriental Research, Jerusalem, describes in *Man* for March interesting results obtained from a surface examination of mounds in the Middle Euphrates region which throw a light on the comparative ceramics of the æneolithic and Early Bronze periods. The site of the finds, Tell Zeidân, is a mound about 500 metres in length stretching along the eastern bank of the Balîkh river. It is covered with potsherds and flint artefacts, the former being nearly all of a creamy white or light buff, covered with geometric designs in black or reddish brown, applied both with and without a slip, in the former case on the buff ware. Only one polychrome sherd was found. It showed alternating bands of black and brownish red on a white slip over a light buff paste. The result of a comparison of this pottery with that from Abû Shahrein, Tell el 'Obeid, and other sites in which the proto-Mesopotamian ware has been found, and a study of the material as a whole, suggests a similarity, which almost amounts to an identity, in all the pottery from north-western Mesopotamia, Babylonia, and southern Susiana in the pre-monumental age. Its place is taken by incised ware in the third millennium. A possible dating may be given by taking Susa I. as falling in the first half of the fourth millennium, Tell Zeidân about the middle, the early occupation of Eridu and Tell el 'Obeid as slightly later, and the painted ware of Kerkut as belonging to the second half of the fourth millennium.

YOUNG FISHES.—The literature on the behaviour of aquatic animals by day and night receives a contribution from Dr. A. C. Johansen, who discusses the diurnal vertical movements of the young of some fishes in Danish waters (*Meddelelser fra Kommissionen for Havundersogelser. Serie Fiskeri* Bd. 8, Nr. 2, 1925). Dr. Johansen produces observations obtained from catches made with a stramin ring-trawl. The paper contains results of a serial collection taken every two hours throughout the twenty-four on April 20-21, 1925, in the southern Kattegat, and a comparison of a number of hauls taken at different stations in the Kattegat, Belt Sea, and western Baltic in the same month by day and night. Two water-layers were sampled, the surface and an intermediate layer estimated as being at a depth of about 16 metres. The catches showed that the average number of post-larvæ of any one species caught was greater at night than in the daytime in the upper water layers, and the same held good for the number of fish species. This demonstrates the necessity for stating the time at which hauls are made when studying the horizontal and seasonal distribution of young fish The writer considers that, at any rate for the smaller stages, the results represent an actual migration from deeper layers at night, and that in the day-time the majority keep down below 16 metres; but that for the larger more swiftly moving forms, there is a probability that they can avoid the net in the daylight, so that no definite conclusions can be drawn. A short report is given of the plankton results obtained, and also of previous work and theories as to causes of vertical migration. Perusal of this paper only emphasises the need for more observations at sea.

THE FAUNA OF SARAWAK.—The *Sarawak Museum Journal* for December 1925 is devoted to a series of papers describing the collections made by Dr E. Mjöberg in northern Sarawak. It is a region which affords great opportunities to the biologist, and the fact that the collections include many new species is to be expected from a part of the world so little explored. Among the insects, Dr. H. H. Karny reports on the katydids (Tettigoniidæ), cricket-locusts (Gryllacridæ), and Copeognatha. Dr. R. Hanitsch, in dealing with the Blattidæ, lists no less than 55 species, among which 24 are described as new to science: perhaps the most interesting feature with respect to this family is the almost entire absence of cosmopolitan forms—a fact probably associated with the absence of the white man in the region concerned The Collembola form the subject of a paper by Dr. H Schott and, with one exception, all the 12 species recorded by him are new, and three new genera are also erected. The Amphibia and Reptilia from Mt Murud comprise only 14 species, and of these, five are described as new by Mr. Malcolm H. Smith The discovery of a new lizard allied to Phoxophrys is of particular note, as is also that of a tree-frog (*Philautus mjöbergi* sp nov.) which was found depositing its eggs and breeding in the pitchers of Nepenthes. In a second paper Mr. Malcolm Smith reports on the more extensive collections made over a wider area of Sarawak during the past two years. They comprise some 700 specimens representing 95 species. The most noteworthy are a diminutive form of toad allied to Megalophrys, which appears to represent a new genus, and an undescribed ground-gecko of the genus Gonatodes. There are two short notes on birds: Dr. E. Hartert describes a peculiar form of flycatcher, and Mr. Einar Lönnberg directs attention to an apparently new race of flowerpecker.

ANATOMY OF HENDERSONIA.—Mr. H. Burrington Baker has been studying and gives a minute description of the anatomy of *Hendersonia occulta* (*Acad. Nat. Sci. Philad.*, 77), which he considers to be the most primitive living example of the family Helicinidæ. His conclusion is based on the fact that

Hendersonia retains a right auricle and a metamorphosed right kidney in both sexes. With respect to the first of these characters, Hendersonia is fully as generalised as any neritid, while as to the second it seems even less specialised. The Neritidæ cannot be considered as in any sense ancestral to the Helicinidæ, although their aqueous habitats have permitted them to retain certain markedly primitive characters, while the terrestrial life of the Helicinidæ can be correlated with an increase in specialisation along several lines. While the homologies between the Rhipidoglossa and the Pulmonata are extremely hypothetical, the genitalia of Hendersonia and the Helicinidæ perhaps can be tentatively regarded as representative of an intermediate stage between those of the less specialised members of the former group and those of the latter. Both the Helicinidæ and the Pulmonata show a marked tendency towards the concentration of the cerebral, pleural, and, to some extent, the pedal ganglia. The nervous systems of these two pulmonate groups actually prove the more usual conception of separate evolutions from common, probably marine, ancestors.

A Bot-Fly Parasitic on Monkeys.—Under the title *Zoopathologica*, the New York Zoological Society has recently established a journal devoted to the publication of its scientific contributions dealing with animal diseases. In vol. 1, No. 7 (January 1926), Messrs. R. C. Shannon and C. T. Greene record the occurrence of larvæ of Cuterebra in certain primates. One lot of material consisted of the neck portion of the skin of a howling monkey (*Alouatta palliata inconsonans*) from Darien, Panama. It was so heavily infested with larvæ that the skin is described as resembling a collection of cells in a bumble-bee's nest. The other lot of material consisted of two bred flies and a number of larvæ taken from a red howling monkey at Kartabo, British Guiana. Probably all the material belongs to the same species of Oestridæ which is described as *Cuterebra baeri* sp. nov. from that obtained at Kartabo. Little is known of the habits of Cuterebra, but, from what is known, the eggs are probably laid about the haunts of the hosts, possibly on the leaves of the plants. It is suggested that if the leaves be eaten by the host animal, the larvæ hatch in the mouth and, boring their way through the tissues, eventually reach the skin of the throat region. Here they make breathing holes and remain in subcutaneous pockets until fully grown. When mature they work their way out and fall to the ground where they pupate.

Fertilisation in a Cycad.—Prof. A. Anstruther Lawson, of the University of Sydney, publishes in the *Transactions of the Royal Society of Edinburgh* (vol. 54, part 2, No. 6, 1926) a most interesting account of the processes preceding, accompanying, and following fertilisation in the cycad genus Bowenia. This Australian cycad has not been readily accessible to botanists, but the selection of the district in which the plant is native as a centre for fruit-growing, has enabled Prof. Lawson to obtain an uninterrupted supply of cones, collected twice weekly throughout the year. The result is a very full account of the cytology of the reproductive organs and of the process of fertilisation. The massive sperms, with spiral ciliated band bearing thousands of cilia, have actually been seen moving in living material, as they swim in the archegonial chamber. Prof. Lawson describes the dilated neck cells of the archegonium as excreting a fluid which adds to the liquid in which the sperms are moving, and also as acting as 'swinging gates,' which are forced apart by the entrance of the sperms, to close again behind them. Interesting figures of nuclear structure following fusion also suggest that the chromatin of the male and female nuclei remains distinct; the spindle in the first division after fertilisation is a broad one of double organisation, maternal and paternal chromosomes dividing and separating independently.

Flow of Swedish Rivers.—In Band 3, No. 5 of *Meddelanden från Statens Meteorologisk-Hydrografiska Anstalt*, Dr. G. Slettenmark gives a mass of data on the flow of the chief Swedish rivers, illustrated by a map showing the location of the gauging stations. The first table gives a list of the 187 stations, the area of the lake basins on the river, and the total area of the river basin. This is followed by tables giving the mean and extreme value of the flow during each month of the year and other useful values calculated from these figures. Many of the stations date back to 1910, but others are of more recent origin. The publication affords exhaustive information on the hydrography of the Swedish river systems. The very brief discussion of the data is in Swedish.

Does a Faraday Cylinder measure Electron Currents?—We have grown so accustomed to measure electron currents by means of a Faraday cylinder through a hole in which the electrons entered, that a short note in the January issue of the *Proc. Nat. Acad. of Sci.*, Washington, throwing doubt on such measurements, is somewhat disconcerting. It is by Mr. E. O. Lawrence, a National Research Fellow working at Yale University under Prof. Swann, and gives an account of measurements of the currents entering a Faraday cylinder 2·2 cm. diameter through a hole of 1 cm. diameter when the length of the cylinder and the accelerating or retarding potential between the tungsten filament emitting the electrons and a plane anode between the filament and cylinder were varied. The anode was placed 4 cm. from the filament and the electrons passed through a hole 0·2 cm. in diameter in it. Curves of current received in terms of the retarding potential and length of cylinder show that a Faraday cylinder does not retain all the electrons which enter it, and it follows that measurements of the speeds of electrons depending on retarding potential observations require revision.

Soap-Boiling Process.—A further contribution to the knowledge of the equilibria underlying the soap-boiling processes has been made by J. W. McBain and W. J. Elford by a study of the potassium oleate–potassium chloride–water system, described in the *Journal of the Chemical Society* for February. The solutions were examined in polarised light, and from the results, equilibrium diagrams for the systems water–potassium oleate and water–potassium oleate–potassium chloride were constructed, clearly showing the limits of existence of the various soaps.

Vapour Pressures of Arsenic Trioxide.—The determination of the vapour pressures of arsenic trioxide up to 500° C. made by E. R. Rushton and F. Daniels, is described in the *Journal of the American Chemical Society* for February. The apparatus consisted of an evacuated Pyrex flask, fitted with a Gibson diaphragm and heated electrically in a metal bath. The published data include the melting and transition points, heats of fusion, vaporisation, and transition of the various allotropic forms of arsenic trioxide. The exact relation between the amorphous glassy form and the crystalline forms has always been rather obscure, and it is to a large extent cleared up by this work.

The Geographical Distribution of Fresh-water Eels.

THERE is scarcely anything in Nature more wonderful than the facts concerning the migrations and life-histories of the fresh-water eels of Europe and America brought to light by the long and persevering researches of Dr. Johannes Schmidt. He has now completed a general survey of what is known concerning the distribution of all the species of the genus Anguilla The first part of this survey, including only the Atlantic Ocean and adjacent areas, was published sixteen years ago The memoir under notice[1] is the second part and is devoted to the Indo-Pacific region, but it contains certain important additions to the information contained in Part I., and references to the chief general conclusions of that part.

The species of Anguilla seems as a rule to be geographical species, though in some cases two or more occur in the same locality. In the Atlantic region there are only two, *A. vulgaris* on the eastern side, *A rostrata* on the western, the former having a larval period of three years, the latter of only one year. Dr Schmidt tells us that in the Indo-Pacific region, at the beginning of his inquiry, the determination of species was generally uncertain, the distribution obscure, and the biology altogether unknown. Some of the uncertainty with regard to species has been remedied, but the thorough investigation of the bionomics still remains for the future

The world distribution of the whole genus shows some curious features. In the Atlantic the contrast is between north and south. On the eastern side eels are found on all the coasts of Europe and North Africa from near the Tropic of Cancer to the White Sea, including all the Mediterranean and Black Seas and the Baltic On the east side, the range of the American species extends from Labrador to the West Indies, and includes a short stretch of the South American coast at the mouth of the Orinoco. No eels occur on the east coast of South America south of this part, or on the west coast of Africa south of the Tropic of Cancer.

In the Pacific, on the other hand, there are no eels on the east side at all from Alaska to Tierra del Fuego, while on the west they are found, often in great abundance, from Japan along the coast of China, in the Philippines, on the northern coast of New Guinea, the east coast of Australia, in both islands of New Zealand, and in nearly all the western islands of the Pacific. From the Sandwich Islands and the Galapagos farther east they are absent.

Eels occur on most of the coasts of the Indian Ocean, except the Arabian Sea and the south-west coast of Australia. With the exception of the short extent of coast from the north of Norway to Archangel, and an unimportant occurrence in Greenland, there are no eels in the Arctic or Antarctic regions. Another curious contrast is the entire absence of these fish from the shallow sea (less than 100 fm.) bounded by Siam, the Malay Peninsula, Sumatra, Java, and Bor while they pass in very large numbers over the at a similar depth on which the British Islands situated. Dr. Schmidt concludes that the ee immigrating from the depths of the ocean are, in case of the Indo-Malayan species, inferior in migra powers to those of the Atlantic species. Eels do migrate through shallow sea-areas in the larval st but only after the metamorphosis, when they reached the elver stage

Although eels are so abundant in individual temperate regions, the greater number of spe belong to the tropics, and Dr. Schmidt believes the genus originated somewhere in the equato Pacific, and that the species have radiated out f this centre. The most widely distributed of tropical species seems to be *A. mauritiana*, wh occurs in the islands off the east coast of Africa, in Philippines, and in many of the islands of the Pac In the Philippines it reaches a large size, some sp mens measuring 2 m. in length and 46 cm. in circ ference. The oceanic larva or leptocephalus of species was obtained and identified by Schmid Celebes in 1925. The ascent of great swarms of el from the sea to fresh water seems to be as famili sight in Japan as in Europe, and to occur at ab the same time of year.

Apart from Europe and North America, Japa the only country where eel fisheries have develo to a large and important industry. In New Zeal two species have been distinguished, *A. australis* *A. aucklandi*, and specimens occur up to 6 ft length, 20 in. in circumference, 46 lb. in wei They are used as food only to a slight extent by European inhabitants, but are caught and eate considerable numbers by the Maoris

The memoir concludes with a section enti "General Observations," in which the author cusses the probable life-history of *A. japonica*, the absence of a species of eel on the eastern sid the Pacific. He considers that the Japanese resembles the American *A. rostrata*, having a la period of about one year, and spawning in the re of the ocean to the south of Japan, where the t peratures at 400 m. are higher than elsewhere in North Pacific. He suggests that the reason for absence of eels on the eastern side of the Pacific is absence of a species having a larval life sufficie prolonged to enable it to make the long migra from the same spawning region to the eastern sid that ocean, since both *A. rostrata*, the Ameri species, and the *A. vulgaris* of Europe, have b shown by Schmidt to carry on their reproductio the western part of the North Atlantic. This d not, however, explain the absence of eels from b the east and west shores of the South Atlantic.

Like other publications of Dr. Schmidt on researches into the characters and bionomics of fre water eels, this memoir shows his mastery of subject, his command of the English language, his skill in clear and orderly statement.

The Construction of Regular Polygons.[1]

JUST as the sequence of propositions arranged by Euclid to form the first book of his "Elements" reaches its climax in the proof of Pythagoras's theorem, so those in the three succeeding books culminate in the construction of a regular pentagon. In the eyes of the Pythagorean school of Greek mat matics, the five regular solids were considered to symbols of perfection. So one of the aims of the f four books of the "Elements" was to supply accep reasoning that would lead to the construction regular polygons of three, four, and five sides— only ones which can be the faces of a regular solid

No further advance in the theory of construct lar polygons was made until the time of Gauss, at the end of the eighteenth century, showed the construction of a regular p^m-sided polygon, ing prime, depends on a succession of algebraic tions the degrees of which are the prime factors $^{-1}(p-1)$ Any quadratic equation being solved he intersections of a line and a circle, it follows a regular polygon of 2^m+1 sides, when this ber is prime, can be constructed by Euclidean ietry. The chain of quadratic equations leading he value of $\cos(2\pi/17)$ in radicals was fully ssed by Gauss ("Disq. Arith," § 354). Various rs have dealt with the geometrical construction regular 17-gon, and it seems unlikely that any ovement in Richmond's construction (Hudson's ler and Compasses," p. 34) will be possible. elot (*Crelle's Journal*, Bd. 9) dealt with the ence of seven quadratic equations which give $2\pi/257$) in radicals, and the same problem has treated geometrically by Affolter and Pascal *oli Rendiconti*, 1887). Euclid's argument which to the construction of a regular quindecagon e extended to apply to regular polygons of 680 55 × 256 × 257 sides, so, in theoretical discussions, ufficient to consider regular polygons of p^m sides.

---

[1] "The Scientific Construction of the Regular Heptagon with Angles Correct to Ten Seconds, derived from Two Crossed-Parallelograms of a Semi-Ellipse." By T. Alexander.

ere are at least three methods of approximately ructing a regular polygon of any number of sides uclidean geometry. First, since

$$\frac{1}{n}=\frac{a_1}{2}+\frac{a_2}{2^2}+\ \ldots\ +\frac{a_m}{2^m}+R_m,$$

$a_r=0$ or 1 and $0<R_m<2^{-m}$, an angle $2\pi/n$ e constructed by m repeated bisections of a angle with an error less than $\pi/2^{m+1}$ Bisection ry small angles can be avoided by a rearrange- of the expansion for $1/n$

second method depends on the formula

$$b^2+c^2-a^2=2bc\cos A,$$

equivalent one, in which appropriate rational s of a, b, c render $A\sim 2s\pi/n$ as small as may be d. Until data are available an element of e enters into the application of this process, being no rule for obtaining *small* rational values b, c to give A within a prescribed limit of error $/n$.

the third method a diameter AOB of a circle, r, is divided into $n-1$ equal parts at points of K is the second from B. Then C being a point e perpendicular diameter such that $OC=\frac{1}{2}\pi r$, uts the circle at Q (beyond the diameter) and $=\alpha=2\pi/n$ with an error of the order $1/n^2$. A more accurate construction is given by

$$KB=4r/(n-\tfrac{1}{2}\pi^2+4)=4r/(n-0\cdot 93),$$

the discrepancy in α then being comparable with $1/n^3$. (A curious but widespread fallacy, of which it would be interesting to know the origin, is that, in the same figure,

$$OC=r\sqrt{3},\quad OK=r(n-4)/n.$$

This rule does not even give a good approximation to a regular figure, the error in α being about 10 per cent when n is large. A much better approximation, avoiding the introduction of π, is given by

$$OC=\tfrac{1}{2}(\sqrt{2}+\sqrt{3})r,\quad OK=r(n-5)/(n-1),$$

this reducing the error in α to ½ per cent. for sufficiently large values of n)

When n is such that the ruler and compasses allowed by Euclid fail, the vertices of a regular n-agon inscribed in a circle can always be obtained as the intersections of algebraic curves with the circle. The curve used to deal with an algebraic equation of degree q, a prime factor of $p^{m-1}(p-1)$, should be one which can be constructed by some simple mechanical means and crosses a curve already drawn in q new points. A cubic equation being always soluble by the intersections of a conic section with a circle, one conic, combined with ruler-compasses geometry, is sufficient when $n=7, 9, 13, 97, 193$, whereas two conics are needed for $n=19, 27, 37, 73$ and three when $n=81, 109$ A suitable conic is an ellipse the foci and major axis of which can be constructed by Euclidean geometry, the usual string and pins process then being available.

Prof. Alexander, in the pamphlet now before us, attempts to construct a regular heptagon, and a reviewer must examine what success has attended his effort In the first place, his constructions, all of which require intricate figures, are approximate · a more accurate approximation to $2\pi/7$ could cer tainly be obtained by drawing a triangle with sui able rational sides a, b, c. Secondly, one constr tion involves the use of a point P on an ell [illegible] such that $\angle PAA'=2\angle PA'A$, A and A' being [illegible] foci: this point P is not defined as the interse of the ellipse with a line or a circle Thirdly, [illegible] most accurate construction, two ellipses are ne to give an approximate value of the angle of a reg heptagon, whereas one ellipse combined with [illegible] and compasses should give the vertices of the hepta exactly. So, for three distinct reasons, we are una to accept Prof. Alexander's constructions as the fin word on the question of the regular heptagon

W. E H. B.

The Malthusian Principle and Sociology.[1]

E variations of the birth rates and death rates in the different countries are most easily studied the diagrams made of them by Dr. C. V iale, the president of the Malthusian League rates remained high, except in France and d, until 1876. Then the birth rate of England, um, Holland, Germany, Austria, and Switzer- and of Europe as a whole, suddenly began to This sudden onset of declining fertility must been due to contraception. The death rates ith the birth rates, and in such close corre- ence as to show that the fall of the death rates losely related to the fall of the birth rates. the progress in medical science and sanitation d the death rates in such close parallelism he birth rates can scarcely have been a co- e. Moreover, when one examines the vital statistics of Rumania, Chile, and Jamaica, and of Russia from 1881 to 1901, and of Ireland from 1886 to 1911, one finds a horizontally-oscillating or fairly stationary birth rate and a similar death rate. Why were not medicine and sanitation reducing the death rate of any of these countries when their birth rate was stationary? Furthermore, Bulgaria, Ceylon, and Japan had a rising birth rate and a rising death rate from 1881 to 1911 Why did these countries then have a rising death rate notwithstanding medical progress?

Evidently, as Malthus believed, the populations of all the long-settled countries were pressing on their means of subsistence—that is, were not increasing their food supplies fast enough for their needs. For example, consider England In 1876 the birth rate and death rate were still very high and the average duration of life only about thirty-five years. Then the birth rate fell or new mouths were added more slowly, and there steadily declined the proportion of persons dying prematurely from diseases consequent upon under-nutrition, thus the death rate fell steadily and the average duration of life rose. The under-nourished are doomed to premature death no matter how efficient and active the health services may be; nothing can make a population increase faster than the food supply; if there be ten additional persons, and only food for eight, two must soon die. The high correlation between the birth rate and the death rate continued up to 1913; therefore, food shortage was still the cause of what was excessive in the death rate up to 1913. Thus the whole of the fall of the death rate from 1876 to 1913, the big reduction of poverty, and the rise in the average duration of life from about thirty-five years to more than fifty years, must be attributed to the decline of the birth rate steadily reducing the amount of the food shortage.

---

[1] ract of a paper read by Mr. Binnie Dunlop, M.B., on February 23, ociological Society.

In all the other old countries, and not excluding France, one may similarly infer that up to 1913, notwithstanding the extent to which the birth rate had fallen in some of them, the population was still pressing on the means of subsistence. The main conclusion is most encouraging and is as follows: Virtually the sole economic difficulty which besets man is that he can only increase his food supply very slowly; consequently, small families and willing work would eliminate poverty.

University- and Educational Intelligence.

CAMBRIDGE.—The Allen Scholarship has been awarded to Ralph Cooper, of Trinity College.

The list of those who have recently passed the qualifying examination (in elementary mathematics and mechanics) for the Mechanical Sciences Tripos hows that twenty-three per cent. of those who were uccessful had not yet come into residence The rriculum for this examination can usually be dealt h at school, and it is of some satisfaction to realise the slow but steady rise in the standard attained e schools is gradually relieving the university of ad of elementary teaching, for which it is often oo well equipped, and with which it really ought o be encumbered

Alfred and Lady Yarrow have offered to ow an Eric Yarrow lectureship for the study of syriology.

Dr. D. Stockdale, of King's College, has been elected a fellowship at that College. He has taken both parts of the Natural Science Tripos and was elected to a Senior "1851 Exhibition" studentship in 1923

MANCHESTER.—The following have been recommended for the honorary degree of D.Sc: Mr. S. L. Pearce, Electricity Commissioner, formerly Consulting and Chief Engineer and Manager, Electricity Department, Manchester Corporation; Prof. A. C. Seward, Vice-Chancellor of the University of Cambridge, professor of botany there; Dr. A. E. H. Tutton, formerly H.M. Inspector of Schools (Technological Branch), Board of Education.

THE British American Tobacco Co., Ltd., has sent a donation of 105*l*. to the funds being collected for the development of the Imperial College of Tropical Agriculture, Trinidad. March 31, 1870.	Sir William J. Pope, K B E. F.R.S.
March 31, 1859.	Sir Frederick W Andrewes, F.R S.

Maj.-Gen GREELY, polar explorer and telegraphist, was born at Newburyport, Mass. He served in the Civil War, 1861–65, and, we believe, was the first volunteer private soldier to reach the grade of brigadier-general, U.S.A. In 1881 he was placed in command of the United States official expedition to establish one of a chain of thirteen circumpolar stations, his party of twenty-five reached farther north than any previous record, discovered new land north of Greenland, and crossed Grinnell Land to the Polar Sea. The final story of the Greely Expedition was one of disaster · there were only seven survivors General Greely was the United States delegate at the International Telegraph Conference, London, 1903 Under his supervision 3900 miles of telegraph lines, submarine cables, and wireless were installed in Alaska, 1900–4.

Prof. KARL PEARSON was educated at University College School, London, and King's College, Cambridge. He was called to the bar, Inner Temple, 1882. Galton professor of eugenics in the University of London, and editor of *Biometrika*, he has written many memoirs on the mathematical theory of evolution and on heredity.

Sir ALFRED EWING, president of the Royal Society of Edinburgh, was born at Dundee. Formerly professor of mechanism and applied mechanics in the University of Cambridge, he was afterwards (1903–16) Director of Naval Education. Since then he has been Principal and Vice-Chancellor of the University of Edinburgh. He was awarded a Royal medal by the Royal Society, in 1895, for researches on magnetic induction in iron and other metals.

Sir JOHN SCOTT KELTIE was educated at Perth, and the Universities of St. Andrews and Edinburgh. For a number of years he was assistant editor of NATURE Sir John was secretary of the Royal Geographical Society, 1892–1915

Sir DUGALD CLERK was born in Glasgow. He is universally known as an investigator in the problems of internal combustion engines. The Albert medal of the Royal Society of Arts was allotted him in 1922, "in recognition of contributions . . . to the development of the internal combustion engine, which in its latter forms has rendered aerial navigation possible, and is also extensively employed in the motor-car and in the submarine." Sir Dugald was a Royal medallist of the Royal Society in 1924.

Sir WILLIAM POPE, professor of chemistry in the University of Cambridge, is a Londoner. He was educated at Finsbury Technical College and the Central Technical College, City and Guilds of London. After a professorial career at the University of Manchester, he became head of the Chemistry Department, Goldsmiths' Institute, New Cross. Sir William was Longstaff medallist of the Chemical Society, 1903, and Davy medallist, Royal Society, 1914.

Societies and Academies.

LONDON

Royal Society, March 18 — **S Chapman**, **J. Topping**, and **J Morrall** : On the electrostatic potential energy, and the rhombohedral angle, of carbonate and nitrate crystals of the calcite type Calculations have been made of the electrostatic potential energy of ionic lattices of the calcite type and for the sodium nitrate crystal, in which the lattice is of the same geometrical type, though the ionic charges are different. It seems probable that, owing to the fourfold positive charge in the C ions, the O ions of the CO_3 group will be distorted from their natural symmetrical form, and consequently the electrostatic centre of the O ion will be nearer to the C nucleus than the O nucleus is The calculations indicate that the electrostatic centre of the O ion is 0·9 Å U distant from the centre of the C ion, compared with the value 1·25 Å U given by X-ray measurements for the distance between the O and C nuclei. A similar result is obtained for $NaNO_3$. — **G I. Finch** and **L G. Cowen** : Gaseous combustion in electric discharges. Pt. I. Steady direct current electric discharges are passed through electrolytic gas at 20–100 mm pressures, and the rate of steam formation measured for varying conditions It is found that the rate of combustion is determined only by the current, and up to a certain limiting current, combustion is confined to the cathode zone, depends upon the cathode material, and is directly proportional to the current. On exceeding this limiting current, combustion commences *abruptly* in the inter-electrode zone and is superposed upon cathodic combustion. This inter-electrodic combustion is also proportional to current, but, unlike the cathodic, is independent of the electrode material, and dependent upon gas pressure and separation of the electrodes. Little or no combustion takes place in the anode zone. Combustion seems to be primarily determined by ionisation of the gaseous medium for the current. The abrupt superposition of inter-electrodic combustion suggests a quantum effect, combustion in the inter-electrode zone depending upon a certain limiting potential fall being attained — **C N. Hinshelwood** and **W K Hutchison** : A homogeneous unimolecular reaction the thermal decomposition of acetone in the gaseous state. The temperature range used was 506° to 632° C. The heat of activation is 68,500 calories, and the results can be summarised by the equation $l_e k = 34{\cdot}95 - 68{,}500/RT$. Calculation shows that the number of molecules reacting per second is about 10^8 times greater than the maximum number that could be activated by collision. The absolute rate at 835° Abs is the same as that of the nitrogen pentoxide decomposition at 328° Abs — **H. Lamb** : On wave resistance. The case considered is that of a solid of dimensions small compared with the depth below the free surface, travelling horizontally under water. Various particular cases of this have been worked out. There appears to be room for a more general investigation in which no assumption is made as to the form of the solid. The device employed for calculation of the resistance is to introduce small frictional forces, and to equate the work done against resistance to the dissipation of energy — **C. E. Eddy** and **A. H. Turner** : The *L* emission series of mercury. — **G R. Goldsbrough** : The properties of torsional vibrations. In order to bring out clearly the nature of the torsional vibrations in reciprocating engine shafts, a simplified model is chosen which emphasises the main characteristics. Even when friction is great, there are two critical speeds of shaft rotation corresponding to each term in the externally applied force.—**E. T. Hanson**: The theory of ship waves. The oscillations of a fluid under gravity, when the depth is variable or very great, have been worked out in two special cases. The theory is now extended very generally to cover a series of cases in which the fluid may be treated as a sea, bounded by a sloping shore on one side and extending indefinitely on the other. It is shown that, whenever the inclination of the shore to the horizontal is a submultiple of a right angle, the problem can be completely solved, and in each case there is a doubly infinite number of possible modes of motion under gravity. This extension makes it possible to calculate the precise effect of a sloping shore upon the formation of the beautiful wave pattern which often follows in the wake of a ship.—**A. O. Rankine**: The effect of temperature on the viscosity of air. The values of the viscosity of air obtained by Williams (*Roy. Soc. Proc.*, A, vol. 110, p. 141) in the lower part of the temperature range are seriously in error. The conclusion that Sutherland's law of the variation of viscosity with temperature becomes invalid for air at the relatively high temperature of 250° C is not justified.

Geological Society, February 24.—**Gertrude Lilian Elles**: The geological structure of Ben Lawers and Meall Corranaich (Perthshire). The country dealt with lies between Loch Tay on the south and Glen Lyon on the north, and between the Loch Tay fault on the east and the Ericht-Laidon-Tyndrum fault on the west. The line of junction between the Ben Lui schists and the Ben Lawers schists is a mechanical one of the nature of a folded slide, the Ben Lawers slide, the rocks above this slide constituting a veritable nappe, the Ben Lawers nappe. The metamorphic condition of the rocks indicates that the folding now exhibited by them is a relatively late feature of the structural story, and obscures their original relationships, which seem to demand inversion of the beds on a large scale such as would be brought about by recumbent folding.

Physical Society, February 26.—**A. Ferguson** and **I. Vogel**: On the hyperbola method for the measurement of surface tension. When a liquid lies between two plates inclined to one another at a small angle, its surface has a hyperbolic section, from which the surface tension can be calculated. The method has recently been improved by Grunmach. Errors arise, however, from the difficulty of determining the horizontal and vertical axes of co-ordinates. This is met by plotting two linearly related functions of the observations, the surface tension being deduced from the co-ordinates of the resulting mean straight line and the angle between the plates. The latter may be measured either directly or by calibration with a liquid of known surface tension.—**E. A. Owen** and **A. F. Dufton**: The application of radiography to the study of capillarity. The X-ray shadow of a tube has previously been used for determining the diameter of the bore. A similar method has been used successfully for capillarity measurements, and observations were made of the rise of mercury in copper and steel tubes and between vertical copper plates.

Society of Public Analysts, March 3.—**B. S. Evans** and **S. G. Clarke**: An accurate method for the determination of mercury in solution. The mercury (in solution as mercurous nitrate) is deposited on copper and then sublimed. The mercurous solution is percolated for 1½ to 2 hours through a special apparatus (see below), the filter tube of which contains a layer of copper filings. The copper, with the deposited mercury, is washed with water and then with acetone, and afterwards dried, and the mercury is sublimed on to platinum and weighed. Accurate results are obtained in the presence of arsenic antimony or bismuth, and large amounts of copper and nitrates. Hydrochloric acid interferes with the deposition, and must be removed.—**B. S. Evans**: An apparatus for continuous percolation and for filtration in neutral atmospheres. The liquid is made to percolate through a filter tube, with the aid of pressure or suction, into a flask, an open return tube ensuring that the pressure in the main funnel and the flask is the same. When the liquid in the flask reaches the end of the return tube, a difference of pressure is established and the liquid is driven back to the main funnel. For filtration in an inert atmosphere a cylinder of the desired gas can be used as the source of pressure.—**A. L. Bacharach**: Notes on the determination of moisture, calcium and phosphorus in the bones of rats. Conclusions as to the influence of diet, etc., on calcium and phosphorus metabolism are largely based on analyses of the bones of experimental animals. Standardised methods are therefore desirable; a routine method is described, and attention is directed to several possible sources of error.

CAMBRIDGE.

Philosophical Society, February 15.—**A. V. Hill**: Irreversible phenomena in muscular shortening.

March 1.—**F. A. Potts**: The development of a harpacticid Copepod.—**J. Gray**: The growth of fish during the phase of yolk-sac nutrition.—**J. Needham**: Intracellular oxidation-reduction potential and anaerobiosis. The intracellular oxidation-reduction potential of *Amœba proteus* appears to be widely independent of the external concentration of oxygen. *Nyctotherus cordiformis*, an anaerobic protozoon normally living in the frog's large intestine, possesses an internal *p*H of 7·1 and an internal *r*H of 19·0-20·0 under aerobic conditions, while under anaerobic conditions the latter value changes to *r*H 9·5-10·5. Nyctotherus can therefore reduce strongly electronegative indicators. It is significant that the amœba, the *r*H of which is independent of the environmental oxygen concentration, cannot adapt itself to an anaerobic life and dies in conditions under which Nyctotherus will live.—**Sir J. Larmor**: Insular gravity and oceanic isostasy.—**R. Hargreaves**: (1) Relativity in connexion with axial rotation. (2) The problem of relativity in reference to several bodies.—**R. Vaidyanathaswamy**: The general (m, n) correspondence.—**S. Goldstein**: The stability of a strut under thrust, when buckling is resisted by a force proportional to the displacement.

PARIS.

Academy of Sciences, March 1.—The president announced the death of Prof. Kamerlingh Onnes.—**Gaston Julia**: The domain of existence of an implicit function defined by an integral relation $G(x,y)=0$.—**H. Krebs**: A geometrical representation of some transformations of partial differential equations.—**H. Milloux**: A property of meromorph functions at asymptotic value.—**A. Kovanko**: The necessary and sufficient conditions of the integration of suites of functions capable of summation term by term.—**Edgar B. Schieldrop**: The non-holonome deviation.—**R. Dugas**: The geometrical interpretation of the method of Jacobi in the case of a point of variable mass.—**Louis Roy**: The propagation of waves on the elastic line with six parameters.—**E. G. Barrillon**: A mechanical apparatus for tracing hydrodynamical fields.—Marcel **Jacob**: The utilisation of measurements of rotatory magnetic polarisation in the analysis of mixtures. In order to circumvent the difficulty introduced by unavoidable changes in the intensity of the magnetising current, a compensation method was arranged, details of which are given.—A. **Dauvillier**: Researches on electric discharge in gases and the radiations which accompany it.—M. **Aubert** and E. **Aubrée**: An extension of the method of critical solubility temperatures for the analyses of petrols. The calculations are based on measurements of the critical solubility temperatures of the petrol in two different solvents—aniline and benzyl alcohol.—André **Job** and André **Samuel**: Complexes produced by the oxidation of the nickelocyanides in the presence of hydroxylamine. The violet complex compound produced by the oxidation in air of potassium nickelocyanide in the presence of hydroxylamine can be converted into a blue compound by the action, in neutral solution, of mercuric chloride, one cyanogen group being removed. Probable formulæ for these coloured complexes are discussed.—J. **Bougault**: An ether-oxide example of a ketone hydrate.—P **Billon**: Combinations of oximes with zinc chloride. In the preparation of oximes with Crismer's salt, the zinc chloride is usually eliminated at the conclusion of the reaction by the addition of water. In the absence of water, an intermediate compound containing zinc chloride can be isolated from the reaction between Crismer's salt and a ketone, and these substances in contact with water decompose, giving the oxime and zinc chloride.—Georges **Mouret**: The coal basin of Haute-Dordogne. The exactitude of the results obtained by Amiot in this field is confirmed, the exact extent of the basin defined, and the character of its limits recognised.—A. **Maige**. Variations of the threshold of amylogen condensation in various cells of the plant.—Antonin **Nemec**: The humification of the dead layer of forest soils.—L. M. **Bétances**: The diffuse lymphoid formations of the vertebrates — Auguste **Lumière** and Mme. **Montoloy**: Anthrax infection and immunity by the peritoneum

ROME.

Royal Academy of Lincei, January 3.—O. M. **Corbino**: The electronic theory of thermomagnetic phenomena — Livio **Cambi**: A supposed nitroprusside of bivalent iron Doubt is expressed concerning the constitution of the compound to which Ungarelli recently attributed the formula, $Na_4[Fe(CN)_5 . NO],9H_2O$.—Carlo **Severini**: The convergence of the series of orthogonal functions.—Giovanni **Vacca**: New series for Euler's constant, $C = 0{\cdot}577 \ldots$—Mariano **Pierucci**: The total energy of the planets. The "energies" of the various planets may be obtained from that of Jupiter by dividing by simple powers of the prime factors 2, 3, and 5; the differences between the values thus calculated and those actually observed being of the same order of magnitude as the errors involved in the determination of the masses.—E. **Raimondi**: Transformation serving for the study of a current flowing between a sheet and an indefinite plane wall.—D **Graffi**: Investigations on the accidental birefringence of colloids in movement.—C. **Jucci**: Parthenogenesis in silkworms as an illustration of the physiological capacity of individuals and of the race.—Giulio **Cotronei**: The biology of Petromyzon. (iii.) The phenomenon of contraction in the sexual maturity of *Petromyzon marinus*. The processes of sexual maturity in *P. marinus* are similar to those in *P. fluviatilis* and are also accompanied by contraction.—G. **Fadda**: A case of functional regeneration in *Cyprinodon calaritanus*.

Diary of Societies.

SATURDAY, MARCH 27.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Rare Gases of the Atmosphere and their Importance in Atomic Theory (4).

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (Associates and Students Section) (at Neville Hall, Newcastle-upon-Tyne), at 3.—P. S. Lea: Notes on Safety Lamps.—Discussion of Papers by J. T. Pringle: Housing of Workmen; and F. J. Johnston: The Use of Breathing Apparatus in Mines.

TUBERCULOSIS SOCIETY (jointly with Society of Superintendents of Tuberculosis Institutions) (at Cambridge). (Continuation.)

MONDAY, MARCH 29.

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX (at Institution of Mechanical Engineers), at 2.30.—To inaugurate the Association.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Rev. Canon A. Lukyn Williams: The Problem of the Septuagint and Quotations in the New Testament.

INSTITUTE OF ACTUARIES, at 5.—G. H. Recknell: The Bonus Earning Power of a New Business Fund.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Mr. Shattock: Demonstration of Specimens of Pathological Conditions of the Breast.

RAILWAY CLUB (at 65 Belgrave Road, S.W.), at 7.30.—W. J. Mitchellhill: Electricity in Railway Operations.

ROYAL SOCIETY OF ARTS, at 8.—W. F. Higgins: Thermometry (Cantor Lectures) (3).

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—Major T. G. Tulloch: Surface Combustion.

TUESDAY, MARCH 30.

ENGINEERS' CLUB (Manchester), at 1.45.—Annual General Meeting.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Sir Thomas Horder, Bart.: Endocarditis (Lumleian Lectures) (3).

INSTITUTE OF MARINE ENGINEERS, at 6.30.—E. Ford: Some Marine Researches and our Sea Fisheries.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (Annual General Meeting) (at Engineers' Club, Manchester), at 7.—R. B. Matthews: Electro-Farming; or the Application of Electricity to Agriculture.

ILLUMINATING ENGINEERING SOCIETY (at Lighting Service Bureau, 15 Savoy Street), at 7.—H. Lester Groom and others: Discussion on Stage Lighting.

ROYAL PHOTOGRAPHIC SOCIETY (Kinematograph Group), at 7.

RÖNTGEN SOCIETY (at Royal Society of Medicine), at 8.15.—Sir John Thomson-Walker: Radiology in Urinary Surgery (Silvanus Thompson Memorial Lecture).

ROYAL ANTHROPOLOGICAL INSTITUTE (Indian Section), at 8.15.—A. F. Geddes: Some Villages of Western Bengal.

WEDNESDAY, MARCH 31.

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (at 17 Fleet Street), at 5.30.—F. Nasmith: Fathers of the Machine Cotton Industry.—S. Daniloff: Some Unusual American Spinning Wheels.—R. H. Naumburg: Two American Textile Pioneers.

INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at Birmingham University), at 7.—E. V. Clark: Power Factor and Tariff.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (at Neville Hall, Newcastle-upon-Tyne), at 7.—A. Karl: The Analysis of Wave Making Resistance.

FRIDAY, APRIL 2.

SOCIETY OF CHEMICAL INDUSTRY (Glasgow Section) (at Glasgow), at 7.—Annual Meeting.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch, Graduate Section) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—L. Close: Boilers.

SATURDAY, APRIL 3.

SCOTTISH JUNIOR GAS ASSOCIATION (Annual Meeting) (at Royal Technical College, Glasgow), at 7.—Prof. T. Gray: Address.

PUBLIC LECTURE.

SATURDAY, MARCH 27.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. H. S. Harrison: Early Man and his Wanderings.

CONFERENCE.

TUESDAY, MARCH 30.

ROTHAMSTED EXPERIMENTAL STATION, HARPENDEN, at 11.30 A.M.—The Culture and Manuring of Fodder Crops.—Sir E. J. Russell: Rothamsted Experiments on Root Crops.—W. A. C. Carr: Swedes and Kale.—J. C. Brown: Mixtures for Forage Crops.—C. Heigham: Mangolds and Sugar Beet.

CONGRESS.

APRIL 2 TO 23.

JERUSALEM AND BEIRUT, INTERNATIONAL ARCHAEOLOGICAL CONGRESS.

SATURDAY, APRIL 3, 1926.

Broadcasting in Great Britain.

THE Report of the Broadcasting Committee (H.M.S.O., Cmd. 2599, 6*d.* net), to which a brief reference was made in our issue of March 13, is commendably concise and at the same time practical; the recommendations made therein are likely to meet with general approval. The problem which the Committee had to consider, that of advising the Postmaster-General as to the scope of the broadcasting service in Great Britain and as to the management, control, and finance thereof after the expiry of the licence of the British Broadcasting Co. on December 31 next, is one which possesses several features containing special difficulties, not merely in relation to the scientific and technical aspects of the service, but yet more so in relation to various influences, still latent, which it may be capable of exerting on practically the whole range of human activities, political, commercial, educational, recreative, and social.

The Committee appreciates the great value of the work accomplished by the British Broadcasting Co., and properly places its admiration thereof on record; however, it recognises that the progress made in broadcasting since its inception in 1922 has already been so rapid and noteworthy that the organisation laid down for that Company no longer corresponds to national requirements or responsibility.

Having considered the various methods which seem available for the conduct of the service, the Committee, it is evident, felt that the prejudice on the part of a large section of the public against the continuance of a monopoly, sanctioned, supported, and protected by the State, is to-day so marked that, in spite of certain obvious advantages that the existing arrangement possesses, a great outcry would instantly have been raised against any proposal to allow broadcasting to remain in the hands of a body constituted on trade lines for the profit of those composing it. On the other hand, there was no getting away from the fact that, although the control by the State of a service with such far-reaching possibilities as those of broadcasting was absolutely essential, yet in view of the impression which widely prevails that the management of the wireless service already in the hands of the Post Office is inefficient, and the circumstance that it has proved unprofitable, it was certain very considerable opposition would be offered to any proposal which contemplated the transfer to a Government department of the undertaking of the British Broadcasting Co., with the exceptionally complicated features existing in its commercial as well as its scientific and technical side. In these circumstances, the Committee had to find a way out of the dilemma, and it has done so by definitely recommending that the broadcasting service should be conducted by a public corporation—the "British Broadcasting Commission" is suggested as a suitable title for it—acting as trustee for the national interest, and that its status and duties should correspond with those of a public service. It further proposes that the management of the corporation should be vested in paid Commissioners, who should be "persons of judgment and independence, free of commitments, with business acumen and experienced in affairs," in order that they may inspire confidence by having no other interests to promote than those of the public.

It is suggested that the Commissioners—to be not more than seven or less than five in number—should all be nominated by the Crown and hold office for five years, subject to an extension of this term on its expiry. The appointment of a considerable number of advisory committees is also contemplated; it is expected that on them, to a great extent, the duty will rest of ensuring due consideration for particular phases of broadcasting, in relation both to programmes and to scientific progress and research, although ultimately it is the Commissioners upon whom will devolve the task of laying down the general line of policy and initiating experiment and research. The appointment of these advisory committees will be in the hands of the Commissioners, who would, the Committee assumes, gladly consult societies and organisations which are qualified to advise on questions of personnel.

The finance of the Commission receives careful consideration; the view is definitely expressed that "the Commission must be self-supporting and can expect no grant from public funds." The Committee fully anticipates that (i) increasing outlay on plant will be necessary, (ii) the overhead and administrative charges of the new authority will rise, and (iii) the control of programmes will be more onerous than hitherto. It further lays down that outlay on bold experiment should not be meagre, and research, both official and unofficial, should be constant. The Committee is therefore of opinion that the expenditure of the Commission, which, it is recommended, should be empowered to raise capital on the security of its income from licence-fees, may be calculated on the assumption that the present licence-fee of 10*s*. per annum will be maintained in the future. The Postmaster-General, it is recommended, should remain the licensing authority, and continue to collect the licence-fees and be responsible for the detection and prosecution of those who conceal their equipment. He should be completely indemnified against all expenditure incurred by him in relation to the broadcasting service; subject thereto, the duty is imposed upon him of paying to the Commissioners from the licence-fees "an income thoroughly adequate to enable them to ensure the full and efficient maintenance and development of the service." Any surplus after the condition last mentioned shall have been met should, it is suggested, be retained by the State.

The Committee recommends that the Commission should be granted a licence by the Postmaster-General; in the first instance, this should be for a term of not less than ten years. The general framework of this licence should be similar to the existing one of the British Broadcasting Co., and would contain a variety of technical provisions, together with the general powers entrusted to the Commission and specific restrictions imposed in the interests of the State. This arrangement would admit of a complete review of the situation at a later date, and any changes, either in the method of control or in the organisation now proposed, which might be rendered necessary by the development of broadcasting, could then be readily introduced.

The Committee recognises that the British Broadcasting Co. has enjoyed certain advantages owing to the permission it had to use, without royalty, certain transmission patents, the property of the constituent members of the Company, advantages which may not appertain to its successor. However, it does not anticipate that any difficulty will arise in respect of these patents should their continued use be essential to broadcasting, and hints that if, at any time, the owners of patents attempt to impose unnecessarily burdensome conditions in relation to the use thereof by the Commission, Section 29 of the Patents and Designs Act, 1907, may not be without its relevance.

Among other matters not touched upon above, the report contains recommendations proposing that: (*a*) All existing contracts and the staff of the British Broadcasting Co. should be taken over by the new Commissioners; (*b*) the Commissioners should be entitled to all ordinary rights as regards copyright material, but it is considered unnecessary to invest them with any special privilege or preference in the matter; (*c*) the claims of listeners desiring a larger proportion of educational matter should, if possible, be met; (*d*) a moderate amount of controversial matter should be broadcast, provided the material is of high quality and distributed with scrupulous fairness; and (*e*) the prestige and status of the Commissioners should be fully acknowledged and their sense of responsibility emphasised.

A historical summary of the broadcasting service in Great Britain is contained in an appendix to the report, the concluding paragraph of which appropriately shows the growth, quarter by quarter, in the number of wireless receiving licences: at March 31, 1922, the number of licences current was 7690, and had by January 31, 1926, increased to 1,840,268.

Work and Needs of the Smithsonian Institution.

THE Smithsonian Institution is appealing to the American public for an addition of ten million dollars towards its endowment. The grounds of this appeal were put in a very forcible and interesting way by Mr. Austin Hobart Clark, in an address to the American Association for the Advancement of Science, at Kansas City, on January 1. Readers of NATURE know something of the Smithsonian and what it has done. Its general policy has been to encourage research along all lines that do not receive adequate support from other sources, but never to interfere with work done under other auspices. In this way it has led to the establishment of ten technical bureaux, which now proceed as Government establishments, though in close touch with, and sometimes under the supervision of, the Smithsonian. The fields in which the Institution is desirous of expanding are mainly those of astrophysics, oceanography, entomology, palæontology, anthropology and archæology, animal diseases, botany, zoology, intensive exploration, and publications. While far from unmindful of the economic importance of these varied activities, the Smithsonian recognises that the vast extension of applied science and its superior rewards are attracting the best of the younger generation, so that the stream of those to whom we should otherwise look for the elaboration of new ideas and theories is being deflected elsewhere. It will therefore be the aim of the Smithsonian in the future, even more than in the past, to promote research in pure science.

The most detailed part of Mr. Clark's interesting address on the work of the Smithsonian Institution was, as might be expected from his own studies, that dealing with the investigation of the sea. He showed in how many points our knowledge is either lacking or too vague for present-day requirements. In the course of his illustrations of economic entomology, he urged the necessity for exact specific identification by comparison with the types in museums, and incidentally mentioned that new kinds are being described at the rate of about six thousand a year, at which rate he estimates that it will take five hundred years to complete the task. Under "Animal Diseases" he announced that it is proposed to establish a laboratory for their study in the National Zoological Park. The botanical programme includes exploration and study of the plants in Colombia, Ecuador, and Venezuela, where the flora is less known than in any other section of the western hemisphere. The need for bringing all this knowledge, not merely to professional workers, but also to the general public, was strongly emphasised.

Mr. Clark claims that the leadership in science which he is pleased to assign to England is intimately connected with the widespread interest as manifested in the large number of amateur scientific societies. Newspapers and magazines show that the interest exists; on men of science falls the responsibility of providing accurate material and plenty of it. Where stimulus is needed is in the presentation of the results of pure science, and here it is sad to note that increased costs have forced the Smithsonian to suspend its "Contributions to Knowledge" and to reduce the "Miscellaneous Collections" by two-thirds. The Smithsonian Institution is appealing for increased endowment. Founded by an Englishman nearly a century ago, it has greatly assisted the workers of Great Britain as well as those of other countries. Would it not be fitting and gracious that Great Britain too, though from a straitened purse, should make some response to this appeal?

Science and Religion.

Science, Religion and Reality. By the Earl of Balfour, Dr. Bronislaw Malinowski, Dr. Charles Singer, Dr. Antonio Aliotta, Prof. Arthur S. Eddington, Joseph Needham, Rev. Dr. John W. Oman, Dr. William Brown, Prof. Clement C. J. Webb, Rev. Dean Inge. Edited by Joseph Needham. Pp. v+396. (London: The Sheldon Press; New York and Toronto: The Macmillan Co., 1925.) 12*s.* 6*d.* net.

THERE has been of late a recrudescence of interest in the relations between science and religion, and the present book is a solid and important contribution to the study of this question, so fundamental for every thinking man. The book is remarkable also as showing how great a change has taken place in the attitude both of the theologian and of the scientific man towards this ever-present problem. The hearty days are gone when Huxley gave battle to the bishops, and fierce controversy raged through the pages of the serious reviews. In this book the spirit of antagonism is gone, and there is an earnest seeking after not compromise, but reconciliation. The pages breathe a sweet reasonableness, and one almost longs—in unregenerate moments—for a little clashing of swords.

In all seriousness, however, this change of attitude is to be welcomed, for every man must make his peace both with science and with religion if his life is to be complete and harmonious. The change is no one-sided one; the theologian realises more and more that he must frankly accept all the well-established facts of science and jettison ruthlessly outmoded cosmologies and fables of creation; the man of science on his part is beginning to recognise that the principles he finds serviceable in the investigation of the material world cannot safely be erected into a comprehensive philosophy of existence. So both sides abate somewhat of their pretensions, and a working reconciliation becomes possible.

It is very difficult to summarise a book of this kind—the work of many hands, approaching the problem from many different viewpoints—the more so because it is not a symposium, but a collection of papers written independently of one another. There is a short introduction by the Earl of Balfour, and a long concluding article by Dean Inge, which in some measure sums up and appraises the work of the contributors, while remaining a brilliant and individual presentation of the Dean's own views, written from an avowedly Christian point of view with all that skill, competence, and originality which we have learnt to expect from him.

About half the book is historical in treatment, the rest a presentation in different ways of both the religious and the scientific points of view.

Dr. Malinowski, in a well-thought-out and interesting article on "Magic, Science and Religion," based largely upon his own personal researches in Melanesia, succeeds in distinguishing clearly between the spheres in savage life of practical—not theoretical—science, magic, and religion. In his dealings with the world around him, in his activities as hunter or tiller of the ground, the savage is necessarily a practical man of science, depending upon the uniformity of Nature for the return of seed time and harvest time and for success in the chase. Magic is defined as "a practical art consisting of acts which are . . . means to an end expected to follow later on." It is akin to science in that "it always has a definite aim intimately associated with human instincts, needs, and pursuits." It is often an attempt to influence favourably a chancy or inimical environment. Religion has a different function and is pre-eminently social.

> "Religious faith establishes, fixes, and enhances all valuable mental attitudes, such as reverence for tradition, harmony with environment, courage and confidence in the struggle with difficulties and at the prospect of death. This belief, embodied and maintained by cult and ceremonial, has an immense biological value, and so reveals to primitive man truth in the wider, pragmatic sense of the word" (p. 82).

There is naturally at this stage of development no struggle between science and religion, for science is quite undeveloped.

In the next essay, Dr. Singer gives us a scholarly account of the "Historical Relations of Religion and Science," treating antiquity and the Middle Ages in some detail and in a most interesting way, and concluding with the final establishment by Newton of the modern cosmology. This historical survey raises many difficult and important problems into which it is impossible to enter fully here. Why, for example, did science suffer a long eclipse from about A.D. 200 to 1500? Was it the influence of the Church, the authority of Aristotle, or were the causes many and complex? From the Stoics onwards, many forms of religion were definitely hostile to science, and the spirit of free inquiry was—from whatever causes—effectively stifled. Active conflict with religion scarcely arises before the birth of modern science, which Dr. Singer dates about 1600.

Early in the seventeenth century, the work of Galileo and Kepler, following on that of Copernicus, began to bear fruit, and presented men with a picture of the universe differing irreconcilably from the geocentric cosmology of the Scriptures and of Aristotle. Here was a clear-cut issue on which no compromise was possible, and in which right was entirely on the side of science. Astronomy inflicted a serious blow upon the Christian conception of the universe, far more serious than that later delivered by the theory of evolution, for evolution can be regarded by the theologian as merely the means of creation, and the conception of gradual development is not incompatible with the Christian theology. Dean Inge goes so far as to say that to this day the Churches have not really faced the problem of reconciling Scriptural doctrine with the incontrovertible teachings of astronomy:

> "The task has been put off from generation to generation, and to this day little has been done to relieve the strain upon the intellect and conscience of the Christian world. Those Churchmen who airily declare that there is no longer any conflict between Christianity and science are either very thoughtless or are wilfully shutting their eyes. There is a very serious conflict, and the challenge was presented not in the age of Darwin, but in the age of Copernicus and Galileo" (p. 357).

Dean Inge advises the Churches to adopt the honest and sensible policy of recognising that "all theological doctrines which rest upon the geocentric theory must be recast, inasmuch as the results of science are, within their own sphere, unassailable" (p. 360).

The paper by Prof. Antonio Aliotta, which follows, is entitled "Science and Religion in the Nineteenth Century," and brings the story up to modern times. Here we are introduced to questions of philosophy, and the recent revolt against Intellectualism is treated ably and sympathetically. Perhaps we can best sum up Prof. Aliotta's point of view by the following quotation:

> "Science and philosophy strive to order the world of our symbols and concepts into the unity of an idea. But the idea does not exhaust the reality; the articulation of concepts will never bring about the attainment of the fullness of life, in which, therefore, our spirit does not find itself understood. Harmony of thought is not sufficient; we wish to feel ourselves to be truly living souls. We do not wish merely to conceive, we wish

also to realise in sentiment and action the concrete unity of life. That is exactly the meaning of religion. The love of our neighbour and the love of God are at the bottom the same aspiration towards this harmony of the lived experiences " (p. 182).

Philosophical questions are brought into prominence also in the next two papers, " The Domain of Physical Science," by Prof. Eddington, " Mechanistic Biology and the Religious Consciousness," by Mr. Needham, and with the latter may be linked up the acute criticism of Naturalism to be found in the concluding paper.

Prof. Eddington discusses in a lively and vivid way the scope and significance of theoretical physics, especially as affected by the doctrine of relativity, and comes to the conclusion

> " that the external world of physics is in the first place approached by way of consciousness, that it derives actuality and value from consciousness, and that it relates only to certain aspects of the common basis of material and spiritual things. The dance of electrons in the brain is only a partial aspect of the mental states and resolutions occurring, and there is no reason why it should claim to reveal the whole inner constitution by which one mental state leads to another " (p. 214).

We do not know quite what to make of the position taken up by Mr. Needham with respect to biological method. In the first part of his article his enthusiasm for biochemistry rather carries him away. He contends that in these days zoology must give place to, or rather has already become, comparative biochemistry and physiology biophysics.

> " The causes for the change lie deep, but the effect has been a profound infiltration of physico-chemical ideas and terminology into the whole biological field, and this implies a corresponding peaceful penetration of the mechanistic theory of life. This change from comparative morphology to comparative biochemistry is indeed one of the most important factors in the scientific history of the last few decades. It will never again be equalled in importance until comparative biochemistry passes over into electronic biophysics " (p. 224).

Mr. Needham assures us that the mechanistic method has triumphed finally over vitalism and neo-vitalism, confounding under this term such diverse views as those of Driesch and Haldane. His attack on vitalism has much weight when directed against theories that rely on ' vital forces ' or entelechies, and it must be conceded also that no vitalistic theory as yet has been developed into a coherent body of biological doctrine anything like so imposing as the mechanistic scheme; but has the problem not moved a little further nowadays than the mere opposition of materialism to vitalism? No one denies the great value of biochemical research, or the validity of its findings of fact, but some of us feel constrained to question whether physics and chemistry alone are sufficient to give us a real biology. Can biology get on satisfactorily as a mere annexe of the physical sciences, or does it not require concepts and methods of interpretation which shall be peculiarly its own? Biology in this sense could coexist comfortably with biochemistry—the two points of view would be complementary, not antagonistic.

Later on in his paper Mr. Needham seems almost to admit this. He recognises that " although mechanism in biology is perfectly justified and indeed essential, it cannot be applied to psychology," and he outlines a form of animism according to which

> " it is the physical functions of life that physics and chemistry are competent to explain, for such questions as the distribution of animals and the general theory of evolution, which obviously involve the consideration of conscious striving, do not come under their entire dominion. MacBride in a recent essay has spoken of evolution as a vital phenomenon, but, from his actual words, this means no more than that evolution is in part a mental or psychological phenomenon, and in this respect we may fully agree with him " (p. 254)

Just how far down in the scale Mr. Needham is prepared to admit the existence and efficacy of ' mind ' is not very clear, nor whether with McDougall he regards blind purposive striving as an indication of ' mind ' or restricts the term to the conscious manifestations of purpose.

One has the impression that Mr. Needham, having broken with Descartes, has gone some little way towards modifying his fervent belief in mechanism, and may yet go further.

There should be read in connexion with Mr. Needham's paper the able presentation in Dean Inge's article of the anti-mechanistic point of view. He is of opinion that the attempt to explain life and evolution on mechanistic principles has failed and that nothing remains but to explain Nature spiritually. He sees signs of this change of attitude in the interest which is being shown in panpsychism, and directs attention to the remarkable philosophy of Fechner, which is known to English readers mainly through a sketch of it contained in William James's book, " A Pluralistic Universe."

Of the three remaining articles in the volume, two, by Dr. Oman and Prof. Webb, deal respectively with " The Sphere of Religion " and " Science, Christianity and Modern Civilisation " from the point of view of the Christian theology; the other, by Dr. W. Brown, treats in an extraordinarily sympathetic spirit the psychology of religious experience. He finds that there is a distinctively religious experience, a distinctive attitude to, or feeling of dependence upon, the Universe, which can be but partially analysed by psychology, and the content of which cannot be completely exhausted by such analysis.

To sum up our impressions of this notable book—it seems to us clear that science and religion have each their own sphere and function in human life. Science is primarily an intellectual reconstruction of experience; religion is a man's whole relation, mental, moral, and spiritual, to the totality of existence. Religion is not primarily an intellectual effort, an imperfect philosophy, but an attitude of the spirit as a whole. If, on one hand, the man of science recognises the philosophical limitations of his methods, and on the other hand, the man of religion honestly faces and accepts the proved results of scientific research, there seems no reason why they should be in conflict. Danger comes on either side from dogmatism and respect for authority.

E. S. R.

The Phylogeny of Flowering Plants.

The Families of Flowering Plants. I. Dicotyledons. Arranged according to a new System based on their Probable Phylogeny. By J. Hutchinson. Pp. xiv + 328. (London: Macmillan and Co., Ltd., 1926.) 20*s*. net.

IT is an interesting coincidence that two books dealing systematically with the Dicotyledons should appear about the same time. The much-delayed second volume of Dr. Rendle's "The Classification of Flowering Plants" was issued at the close of 1925, and Mr. Hutchinson's work, herein reviewed, at the opening of the present year. The manner of their appearance suggests a prediction to the effect that one marks the close of a chapter and the other the opening of a new one in British systematic botany. The classification of Engler upon which Rendle's useful and informative text-book is based has, we venture to say, run its course, and botanists generally, at any rate the younger school, will welcome this refreshing and originally conceived handbook of Mr. Hutchinson's, with its new classification professedly framed on phylogenetic lines and actually at any rate on sound and stimulating ones.

At present Mr. Hutchinson is publishing in the *Kew Bulletin* a series of papers on the phylogenetic classification of flowering plants, the end in view being, we believe, the production of a *magnum opus* in the shape of a new "genera Plantarum." The present volume is a foretaste—a *parvum opus*—dealing only with the families. It is a means of addressing a larger botanical public than he could hope to reach through the pages of the *Kew Bulletin*.

Since an article appeared in NATURE only a year ago (vol. 115, pp. 340 and 385) on this subject, readers especially interested are referred to this, as space will not permit of the same ground being re-traversed. Hutchinson's principles of classification and his new arrangement of the Archichlamydeæ (Polypetalæ and Apetalæ combined) were there explained and comments made. In this book for the first time his scheme for the Metachlamydeæ (Sympetalæ)—the higher Dicotyledons with corolla in one piece—is outlined, and in his ingenious phylogenetic diagram facing p. 8, he shows how he proposes to derive them from the lower free-petalled orders. He is here still fertile in new ideas, continuing to employ what might be called his *leitmotiv*, namely, the derivation of the Dicotyledons in two branches, one from the Magnoliales with the tree-habit dominant and the other from the Ranales with the herbaceous habit prevailing. The former is considered to have given rise to the Ebenales (possibly straight from the Anonaceæ), the Ericales, Apocynales, and Rubiales; the latter to the primroses, gentians, scrophs, labiates, etc. The Compositæ are regarded as of mixed origin and are no longer given pride of place among dicotyledonous plants. This is now awarded to the Labiatæ.

The book begins with a short, well-balanced foreword by the Director of the Royal Botanic Gardens, Kew. The author's preface follows. Here stress is laid on the distinction to be drawn between a phylogenetic classification and a key. One should emphasise rather the *resemblances* and the other the *differences* between plants. One aims at a truly natural system by striving to discover relationships. The other is purely artificial and constructed solely for the easy identification of plants. Taxonomists in the past, by trying to compromise, have failed on one hand to stimulate inquiry, and on the other to give the most readily worked keys. Hutchinson sets out to keep these two ends in view quite distinct.

The introduction is largely a reprint of his general remarks on classification which appeared in the *Kew Bulletin* about three years ago. A useful table is added contrasting his new system with those of Bentham & Hooker and Engler & Prantl. Then follows the phylogenetic system itself. After this comes the artificial key to the families of the Dicotyledons, 264 in all. This is an ambitious effort, and if workable, as apparently it is, should prove of considerable practical value, especially to botanists and foresters stationed in the tropics.

The descriptions of the families which naturally occupy the greater part of the book are concise and clear. The numerous illustrations, one, in fact, to each family, form a noteworthy and attractive feature. These are from the pen of Mr. Trevithick and the author. Some are original and few are hackneyed. In each figure a flowering shoot of the plant selected to illustrate the family is shown along with enlarged details. No scale, however, is given. One cannot refrain at this point from mentioning the frontispiece. This is from the author's own designing and charmingly represents in floral form the ideas of affinity expressed in this work. It surrounds the appropriate dedication, namely, to the memory of George Bentham and Joseph Dalton Hooker. A strong point is made of geographical distribution, and several maps are given showing family or generic distributions of a restricted or otherwise interesting character. An appeal is made to the economic botanist and horticulturist by enumerating, at the end of each family, plants useful to man. Some reference to the mode of pollination might have increased the value of these descriptions. The book ends with a glossary and index.

Manuals of this kind published in England usually lay stress on the families which are especially exemplified in the British flora. This, though quite understandable, is apt to give the student a restricted and wrongly balanced conception of the flowering plants of the world as a whole. Hutchinson avoids this by treating all families alike. Hence the book is suitable for any part of the world. A companion volume dealing with the Monocotyledons is promised. Eventually we hope that both Dicotyledons and Monocotyledons may be included within the pages of a single book and issued at a cost not exceeding that of the present volume.

This work might have benefited from more detailed inspection when in proof. The mistakes and omissions are chiefly noticeable in the explanations to the illustrations. These are, however, not likely to be misleading.

In conclusion, we should like to congratulate the author in particular and Kew in general on this forward move in taxonomy and the study of the flower. The views expressed as to the inter-relationships of the Dicotyledons should arouse research in this department of botany. Several lines of inquiry will, one imagines, suggest themselves to interested and critical readers.

J. PARKIN.

Principles and Practice of Electrochemistry.

(1) *Principles and Applications of Electrochemistry.* In 2 vols. Vol. 1: Principles. By Prof. H. Jermain Creighton. Pp. ix+446. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 20*s.* net.

(2) *Theoretical and Applied Electrochemistry.* By Prof. Maurice de Kay Thompson. Revised edition. Pp. xix+551. (New York: The Macmillan Co., 1925.) 20*s.* net.

(1) PROF. CREIGHTON'S book on electrochemistry deals exclusively with "Principles," but is to be followed by a second volume on "Applications of Electrochemistry" by Prof. Colin G. Fink. The theoretical volume is a well-balanced treatise, which covers in a satisfactory manner the principal methods of measuring conductivities, ionic mobilities, and electromotive forces, as well as the deductions that can be drawn from these measurements. It is, however, not a very easy matter to write a text-book on theoretical electrochemistry at a time when physicists have declared that, even in the solid state, there is no such thing as a molecule of common salt, but only an aggregate of ions, and when physical chemists are beginning to explore the possibility of applying the same drastic conclusion to salt solutions. What, for example, is to be done in these circumstances with the old hypothesis of Arrhenius, which has formed the basis of all such treatises during the past thirty years, but must now apparently be regarded as obsolete?

As a provisional solution of the problem, the author has adopted the worldly-wise policy of writing his book in terms of the old hypothesis, instead of rewriting it in terms of modern physical conceptions; and he justifies his retention of this hypothesis by quoting with approval a statement of Kendall that "no case has yet been made out for its abandonment." Nevertheless, it is clear from the reservations that he makes, and from the explanations that he gives, that the foundations have already crumbled and must speedily be replaced, even if this involves only an underpinning and not a rebuilding of the old superstructure.

One fascinating application of the newer point of view is made in connexion with amphoteric electrolytes. According to the traditional method of formulation, the un-ionised portion of an amino-acid was regarded as made up of electrically neutral molecules of the type $NH_2 . CHX . COOH$. In the newer system it is natural to regard it as having a similar structure to ammonium chloride, $\overset{+}{N}H_4\overset{-}{Cl}$, and therefore to write it in the form of a bipolar molecule or ***zwitterion***, $\overset{+}{N}H_3 . CHX . CO . \overset{-}{O}$. The effects of this simple change have been worked out by Bjerrum, who has thus deduced an entirely new set of dissociation constants for these compounds. In particular, he finds that the acid dissociation constants of the amino-acids are larger than those of the carboxylic acids from which they are derived, instead of being very much smaller; and their basic dissociation constants are also found to be much larger than was formerly supposed. Thus, in the case of asparagine, the acid dissociation constant is of the order of 10^{-2} instead of 10^{-9}, and the basic dissociation constant is of the order of 10^{-5} instead of 10^{-12}. The theoretical deductions from these altered numbers need not be discussed; but it is at least clear that grave risks are involved in drawing deductions from data that have not been examined in the light of the modern physical theory of atomic structure.

In accordance with a practice which is becoming increasingly common, a series of problems has been added to each of the principal chapters. Experience shows that problems such as these are of great value in fixing the subject matter of the text in the mind of the reader, if he is willing to make use of them, and their inclusion in the present volume is therefore to be welcomed.

(2) Prof. Thompson's "Theoretical and Applied Electrochemistry," based originally upon a course of lectures on applied electrochemistry at the Massachusetts Institute of Technology, appeared first in 1911. The principal change in the second edition arises from a decision to include in the volume a treatise on theoretical electrochemistry as well, in response to suggestions made by readers of the first edition. The sections on "Applied Electrochemistry of Aqueous Solutions" and on "Electric Furnaces and their Products" have, however, also been revised and largely rewritten. The author has received assistance from a large number of those engaged in the electrochemical industry of the United States, and there can be little doubt that his book gives a satisfactory account of the present position of the industry so far as this is available for publication.

The Spirit of Modern China.

From Peking to Lhasā: the Narrative of Journeys in the Chinese Empire made by the late Brig.-General George Pereira. Compiled by Sir Francis Younghusband from Notes and Diaries supplied by Major-General Sir Cecil Pereira. Pp. x+293+33 plates. (London: Constable and Co., Ltd., 1925.) 18*s*. net.

GENERAL PEREIRA'S notes, from which this volume has been compiled by Sir Francis Younghusband, cover three journeys. Of these, the first from Peking to Lhasa and India is the longest and the one of which the account is the most detailed. It is also the most interesting, for the author was the first European to succeed in reaching Lhasa from China since 1848, when Pères Huc and Gabet reached the Holy City from this direction. This journey was in itself a remarkable feat for a man nearly sixty years of age and physically weak; but almost immediately he started on his second journey from Burma to Shanghai, and then, in attempting to traverse China from south to north, he died in 1923 while on his way from Yunnan to Kansu.

Pereira was particularly well qualified for the task he had set himself. He had resided long in China and had visited every one of its provinces, either as a private individual or as an official. His notes of his journey are therefore valuable not merely as a geographical record; they also embody the acute observations on conditions in China in the years 1921–23 of one who was intimately acquainted with the people. In addition, three chapters written by Pereira himself, one in 1921 and two in 1923, summarise his views of the situation. He held that the evils of the imperial system had been multiplied under the Republican Government, while the checks on undue extortion and the influence of the students had been removed. The great dangers, as he saw them, were the facility with which popular opinion might be diverted into dangerous channels, as had happened in the Boxer movement; the student movement with its superficial acquirement of Western ideas; and generally, the lack of discipline in education, due to the weakness in the position of the foreign teacher, and the increase in the numbers of the soldiery, who at the least inducement were liable to become brigands. These factors were, of course, additional to and dependent on the lack of a strong central government. The proposal to abolish extraterritoriality he considered to be due to a misunderstanding of the position outside of the treaty ports, where Europeans lived in conditions which were practically Western.

Subsequent events have largely justified Pereira's views, even if to some little extent these are coloured by his training and mentality. The emphasis he lays on the importance of the student class as the future governors of the country, and his acute analysis of its weaknesses, lend support to the views of those who press the need for the inculcation of a new public spirit in Chinese affairs, and hope that it may be attained through co-operation between Britain and China in extending the facilities for university and secondary school education by means of the Boxer indemnity.

The Kiwai.

Among Papuan Headhunters: an Account of the Manners and Customs of the Old Fly River Headhunters; with a Description of the Secrets of the Initiation Ceremonies divulged by Those who have passed through All the Different Orders of the Craft, by one who has spent many Years in their Midst. By E. Baxter Riley. Pp. 316+16 plates. (London: Seeley, Service and Co., Ltd., 1925.) 21*s*. net.

IN this book we have the observations upon the natives of the region of the Fly estuary by a missionary who has been in the district for twenty-five years, and as he has taken a lively and sympathetic interest in the people under his care, we may accept his account with confidence. Mr. Baxter Riley nowhere refers to missionary work as such; his aim evidently has been to give his readers a knowledge of native life and customs without obtruding the personal element.

The old order is rapidly changing, but the former conditions are not so far distant that they have become seriously obliterated. The author admits that he has omitted certain details which might be considered to be out-of-place in a book designed for the general public, and it is obvious that in a book of this kind a selection must be made. Nevertheless, ethnologists will find a great deal of information which has not previously been published. As a matter of fact, a good deal has been written in English in scattered publications about these people, but mainly from an external point of view, though Dr. G. Landtman has published intensive papers on such subjects as: Wanderings of the dead in the folk-lore of the Kiwai-speaking Papuans (*Festskrift*, E. Westermarck, 1912), the poetry of the Kiwai Papuans (*Folk-Lore*, 1913), Papuan magic in the building of houses (*Acta Acad. Aboensis Humaniora*, 1920), and especially his great work "The Folk-tales of the Kiwai Papuans" (*Acta Soc. Sci. Fennicae*, 47, 1917); but most of these are not readily accessible to the non-specialist reader. This book, therefore, fills a gap in our knowledge of the region, and the accounts of the various ceremonies are of considerable value.

A more detailed account of their ethical ideas, however, would have been welcome, for, after all, the ideas and ideals of a people are the most important phenomena, and it is these which are usually so lacking in ethnographical descriptions; but perhaps a missionary is not always in the best position to obtain these, as they are, as a rule, what he has come to replace, and the natives know this. The three-line paragraph on "The State after Death" is clearly inadequate; fortunately Dr. Landtman has given us full information on this matter. The book concludes with an interesting chapter on the "Psychology of Native Dancing." The book is well illustrated by photographs and native drawings, and there are two maps.

A. C. HADDON.

The Preservation of Food.

Department of Scientific and Industrial Research. Report of the Food Investigation Board for the Year 1924. Pp. vi+80+6 plates. (London: H.M. Stationery Office, 1925.) 3*s*. 6*d*. net.

THE work of the Food Investigation Board ranges from laboratory experiments on the chemistry of foods or allied materials and on the physics of methods of preservation, to large scale investigations on the storage of various foods under commercial conditions, and on the engineering problems connected with this subject. The first section is devoted to the theory of freezing: it has been found that discs of gelatin frozen slowly show an outer shell of ice and an inner core of concentrated protein, while with very rapid freezing there is no external shell of ice, but the ice phase is distributed throughout the gel in the form of small discrete spheres of about 3μ in diameter. Intermediate rates of freezing give intermediate results. The displacement of water involves not only a permanent alteration of microscopic structure but also a permanent molecular change; but the actual separation of water on thawing, as in the 'dripping' of frozen beef when thawed, seems to occur only with a slow rate of cooling when ice separates on the surface of the colloidal material.

Further investigations have been carried out on the freezing of eggs and on the chemistry of muscle. The curious change in the yolk on freezing below $-6°$ C. for a sufficient length of time, whereby it passes into a stiff pasty condition on thawing, appears to be due to an irreversible precipitation of the lecitho-vitellin. It was found also that eggs retain their fertility longest at 8°-10° C., and die at $-7°$ C. Further work has been carried out on the production of lactic and succinic acids in muscle, and a new investigation commenced on the oxidation-reduction potential of the cell interior.

About half the report is taken up with the section on the preservation of fruit and vegetables, most of the work having been carried out on apples. The chemical changes occurring on storage and the conditions favouring or hindering the growth of fungi and the deterioration of the fruit on keeping have been investigated in great detail. The respiratory activity falls off *pari passu* with the acid concentration during the growth of the apple, whether on or off the tree, until senescence sets in, when an abrupt rise occurs. Alterations of respiratory metabolism occurring with 'internal breakdown' lead to the production of acetaldehyde and alcohol; this change is accelerated by a certain amount of carbon dioxide in the external atmosphere and is retarded by a smaller concentration in the presence of oxygen; an atmosphere of pure carbon dioxide is almost as favourable as air with a carbon dioxide content below the critical value. The optimum conditions of storage are difficult of attainment, since the following factors all affect the results: species of apple, nature of soil on which it is grown, season, temperature and atmosphere of storage chamber. Other work has been carried out on the chemistry of oils and fats, and of carbohydrates, including the chemistry of glycogen. The final section is devoted to some engineering problems in refrigeration, and closes an extremely interesting report.

Letters to the Editor.

Rock-lead, Ore-lead, and the Age of the Earth.

IN 1921 Prof. H. N. Russell attempted to fix an upper limit to the age of the earth on the basis of an assumption that all the lead in igneous rocks was of radioactive origin (*Proc. Roy. Soc.*, A, vol. 99, p. 84). He took the proportion of lead as 22×10^{-6} (gr. per gm.) and obtained in consequence a very high maximum age. This proportion appears to be based largely on analyses of rocks from the neighbourhood of galena veins, and is therefore probably not a fair average for igneous rocks as a whole. An estimate more applicable to the problem is provided by an analysis for lead of 329 igneous rocks, made in 1914 by F. W. Clarke and G. Steiger (*Journ. Wash. Acad. Sci.*, vol. 4, p. 58). They found a proportion of only $7{\cdot}5 \times 10^{-6}$. The present proportions of uranium and thorium in average igneous rocks are respectively 6×10^{-6} and 15×10^{-6}, the lead-generating equivalent in terms of uranium alone ($U + 0{\cdot}37$ Th) being $11{\cdot}5 \times 10^{-6}$.

If all rock-lead has been derived from the radioactive elements, then the equivalent amount of uranium must have been $8{\cdot}6 \times 10^{-6}$, giving an original total of equivalent uranium of $20{\cdot}1 \times 10^{-6}$. The time required for this original amount to disintegrate into $7{\cdot}5 \times 10^{-6}$ parts of lead and the corresponding quantity of helium, leaving the existing amounts of uranium and thorium, is approximately 3200 million years.

On the above figures, or on the data for any individual type of rock, granitic, basaltic, or peridotitic, the atomic weight of rock-lead should be a little less than 207. The lead of commerce, which is ore-lead derived almost entirely from the common vein mineral galena, is 207·2; and no significant deviation from this standard figure has been detected. Whatever the age or locality of galena may be, the atomic weight of its lead appears to be in all cases substantially higher than 207. It is therefore certain that ordinary lead cannot have been wholly derived from the radioactive elements during their terrestrial history, and this conclusion leads to two remarkable deductions.

Since an unknown amount of the lead in igneous rocks may be ordinary lead, it is clear that the earth—as a radioactive container—cannot have existed for so long as 3200 million years. This is in accordance with the evidence of radioactive minerals. Uraninites and other minerals from the Middle Pre-Cambrian rocks of Norway, Sweden, Ontario, Texas, Colorado, India, and Mozambique all give ages between 1000 and 1100 million years. The greatest age yet determined is that of a pitchblende from the Black Hills of South Dakota. I am indebted to Prof. A. C. Lane for an analysis of this mineral recently made by Mr. C. U. Davis, of the United States Bureau of Mines. It indicates an age of 1525 million years, and the atomic weight of the lead separated from it has been determined by Mr. L. P. Hall as 206·07. The frequently-quoted figure for the age of the earth, 1600 million years, thus appears to be of the right order, provided that the method, as I believe it to be, is sound in principle.

Accepting this provisional estimate, it follows that roughly half the lead of igneous rocks is of radioactive origin. It also follows that the ore-lead of mineral veins cannot be a concentration of the lead of igneous rocks, as is usually supposed. At least the greater part of the lead of ore-deposits must have been already in existence when uranium and thorium began to generate lead in the crustal rocks. Consequently, unless one assumes that ordinary lead can have been formed within the earth by some other unknown process, it seems safe to conclude that ore-lead must have originated either in the ancestral sun or during the events that attended the birth of the solar system. In the former case it may have been of radioactive origin, but if so it must have been generated during a period over which the average ratio of uranium to thorium was 6 . 16·2, in order that the resulting mixture of isotopes should have an atomic weight of 207·2. The terrestrial ratio is not less than 6 : 15, and if this is a guide to the solar ratio, the latter must in former ages have been greater than 6 : 15 instead of less, because the half-period of uranium is much shorter than that of thorium. On the other hand, if ore-lead is not of radioactive origin, as the argument suggests, then uranium and thorium must either have originated or have become radioactive at about the time of the birth of the solar system.

From the point of view of ore-genesis, the distinction drawn between ore-lead and rock-lead is of fundamental importance. It implies that the ore-bodies in which galena occurs are not derivatives from the igneous rocks visibly associated with them in time and place. J. E. Spurr has already concluded from the distribution of ores that the "magmas" of the latter are not residual fluids expelled from igneous rocks during their crystallisation, but that they are magmas of a special type developed in a zone that is locally a rich storehouse of certain metals.

It is clear that if the atomic weight of rock-lead could be determined, the result, whatever it may be, would throw a searching light on many baffling problems. To separate sufficient lead for the purpose from a representative collection of the world's igneous rocks would be a herculean task, but the value of the result would justify the labour, and I have penned this letter partly in the hope that some great research association, such as those of the United States, may be persuaded to undertake it.

ARTHUR HOLMES.

Miller's Ether Drift Experiment and Stellar Motions.

IN connexion with Dr. Miller's recent announcement (*Science*, 63, 105, 1926) of his results in measuring the 'ether drift,' the writer wishes to direct attention to a few points which may be worthy of interest.

If we suppose that Miller's results are real, and if we try to interpret them as a partial drag of the ether, it is difficult to avoid conflict with known facts about first order (v/c) effects. The constant of aberration and the Michelson-Gale experiment for determining the earth's rotation by optical means give, within the errors of measurement, the full effect expected from theory, whereas Miller's experiment seems to give a greatly reduced effect of an ether drift. But if we interpret his results in terms of what they really are, second order effects (v^2c^2), most of the difficulties disappear.

The displacements measured by Miller correspond to a change in the length of his interferometer of the order 10^{-9}, and his final errors are about 5 per cent. of this quantity. There are probably several explanations for this change in length of his interferometer or in the velocity of light, but if a contraction in the Lorentz-Fitzgerald sense (that is, one due to 'absolute' motion in a stationary medium) exists, it is *only* by experiments of this type that we have as yet been able to determine whether the supposed change in the velocity of light in different directions is *exactly* compensated by the contraction within quantities of this order of magnitude. If this compensation is not exact, the expression for the Lorentz-Fitzgerald contraction, and the fundamental formulæ in the special theory of relativity, require a small but important modification of such a form that the 'absolute' motion enters explicitly into the final expressions. A corresponding modification must also be introduced into the space-time transformations of the general theory, but as these modifications are of the order of only 5 per cent., or more probably 3 per cent., no conflict need arise with the observed facts as regards the tests of the general theory of relativity. But in this case we are obliged to admit the existence of a fundamental reference frame which plays an active rôle in determining physical phenomena.

If the 'absolute' motion does not completely vanish in the case of contraction of matter, it is likely that the expression for the change of mass of an electron requires a corresponding modification, so that the absolute motion enters explicitly. Our ordinary conception of electro-magnetic mass is connected with the way in which the 'field' reacts on the motion of a charged body, and if the mass of an electron is a function of its absolute motion, we may expect a resultant momentum opposing the absolute motion of an atom, but noticeable only when the electron connected with the atom has a velocity approaching the velocity of light. Inside the atoms of the heavier elements, and even more in radioactive processes, electronic velocities occur which approach the velocity of light. As this reaction presumably is exceedingly small, it is difficult to detect. The most promising objects to study are the stars, for which the impulses have opportunity to accumulate for a very long time without being modified by collisions. For a system of stars like our local star system, for which we can assume a community of origin, that is, small initial relative velocities, we may thus expect an asymmetry in the distribution of stellar motions. The motions of the stars in our local system actually show such an asymmetrical distribution and of just such a type as is to be expected from a velocity restriction in a fundamental reference frame in which the globular star clusters and the spiral nebulæ are statistically at rest (*Astrophysical Journal*, 61, 363, 1925). The sun's velocity relative to this 'world-frame' is about 300 km/sec. in the direction $\alpha = 307^\circ$, $\delta = +56^\circ$. Miller claims that his observations indicate a translation of the sun of at least 200 km./sec. in the direction $\alpha = 255^\circ$, $\delta = +65^\circ$, which point is about 23° from the apex as derived from the asymmetrical distribution and from the globular clusters. As the earth's orbital motion is too small to be detected, there is no way, however, of deciding between two opposite directions.

Even apart from a possible positive effect in the Michelson-Morley experiment, there is another reason for suspecting the existence of a fundamental stationary reference frame. The velocities of the stars are in general less than 500 km/sec, and this is ordinarily explained as a result of the fact that the stars have formerly been more intimately connected than they are now, and that objects of excessive velocities have escaped. But astronomers during the last decade have gone far outside our local star-system, and still we find velocities in general less than 1500 km./sec. The assumption of a selective effect or of an exchange of momenta between *all* cosmical systems may be unnecessary; distant systems may even, in a sense, have an independent origin and still have comparatively small initial velocities, if they are 'born' out of a fundamental medium, the metrical properties of which are the same everywhere. Such a medium and a velocity-restriction would also account for the rigidity of the inertial frame and its coincidence, so far as rotation is concerned, with the stellar frame even for the most distant objects observable. The uniformity in Nature is then due to the uniformity of this medium.

There are, however, several difficulties with regard to the possible interpretations of Miller's experiment. Among these difficulties is the predominant westerly deflexion of the 'ether-drift.' Unless unknown disturbing effects are present, the algebraic sum of the east-west components of the drift during a sidereal day must be zero. Among disturbing effects, besides those due to temperature changes, the effect of a magneto-striction ought to be carefully investigated.

GUSTAF STRÖMBERG.

Mount Wilson Observatory,

Nitrogen in the Sun and Stars.

IN a letter in NATURE of February 20, p. 268, under the title "Nitrogen in the Sun," Prof. Saha, in his discussion, refers to the occurrence of nitrogen lines in stellar spectra. He says: "The only nitrogen line which can be identified without ambiguity in the stellar sequence is λ3995. This, however, does not occur in the sun; it occurs, according to [Miss] Payne, first in the A0 class, and Fowler assigns it to N^+." The correction of inaccuracies in these statements may prove of assistance to Prof. Saha in his valuable theoretical deductions appertaining to spectra.

In 1910 the present writer gave ("Researches on the Chemical Origins of various lines in Solar and Stellar Spectra." Publication of the Solar Physics Committee) a list of twenty-nine lines of nitrogen which had been traced in spectra of various subdivisions of the B class. Five of these were, in the stellar spectra, probably blended with lines of other elements, but the remainder were quite free from ambiguity, though a few were weak lines which could not be traced through so long a range in the stellar sequence as the stronger nitrogen lines. Such well-known lines as λλ3995·3, 4447·2, 4630·7 and its four companions on the more refrangible side, are all quite free from blending, the first and third being traced through almost the whole of the B group (B8 to B0) and in ι Orionis of the Oe type, while the remainder were detected only in the shorter range B2 to B0. In addition to occurring in the ordinary stellar sequence, they were observed as absorption lines at certain stages of the spectra of Nova Geminorum by Mr. Stratton, and of Nova Aquilæ by the writer, but in each of these spectra they were enormously displaced to the violet of their normal positions. All the nitrogen lines just mentioned belong to the singly-ionised group designated by Fowler as N^+.

Of the doubly-ionised lines of Fowler's N^{++} class, there is no ambiguity in stellar spectra with such lines as λλ4097·5, 4379·3, 4634·3, and 4640·8. Of these 4097·5 occurs as a weak line at B2 (γ Orionis), is much stronger at B0 (ε Orionis), and apparently attains its maximum intensity in a star of Oe type (29 Canis Majoris), where it is almost as strong as H_δ. This is, however, probably a 'freak' intensity in a star placed, from other considerations, in the Oe class. In other stars of the same named type the line is much less intense. Line 4379·3 is never very strong in stellar spectra, but has been recorded in B2 and B0 types in Kensington publications, and by H. H. Plaskett in O9 and O7 of his suggested classification of O-type stars. It is slightly weaker in 10 Lacertæ (O9) than in 9 Sagittæ (O7), but it is not easy to say where it attains its maximum intensity. Lines 4634·3 and 4640·8 have a different range from the other N^{++} lines discussed here. They have not been traced in any sub-division of the B group. Plaskett records them as absorption lines in O9, and as emission lines in O8 and O7.

All these N^{++} lines occur as emission lines at certain stages of the spectrum of Nova Aquilæ, and probably also in other Novæ. All except 4379·3 have also been recorded in various nebular spectra by Wright. It would seem that the N^{++} class might be further subdivided in the light of their rather different behaviour in stellar spectra.

With regard to Prof. Saha's assertion that, according to Miss Payne, the N line 3995 occurs 'first' in the A0 class, he rather misrepresents her. What she said is: "3995 . . . appears at B0 or earlier, reaches maximum at B5, and is last seen at A0." She was discussing the changes in the line-intensity from B types towards A and later types. This may seem a detail, but in mentioning where a line 'first' or 'last' appears, as Prof. Saha did, it is as well to specify which direction along the stellar sequence an argument is being taken.

It is not here a question, however, of whether the N^{+} lines (3995, for example) are first or last seen at A0, but whether they occur in that type at all. The Harvard type-star for A0 is α Canis Majoris, and in the Harvard tables of stellar lines 3995 does not occur for that spectrum. It was not recorded in the Kensington list of lines for α Canis Majoris, and further search for it in the best spectra available here has not revealed it. It occurs as a weak line in β Tauri (B8), and in β Orionis (B8 Pec.), but that is the latest type in which I have been able to detect it. There is no spectrum of the B9 type in the Cambridge or Kensington collections, but one would rather expect this type to show it as a very weak line. I have always associated these nitrogen lines with the B class of spectra, but never with any subdivision of the A class, and no spectrum has been found here containing the 3995 line which has not the helium lines well-developed. This latter characteristic is not generally associated with A stars, although a few of them (*e.g.* α Cygni) show one or two of the helium lines faintly.

In the light of the table given in the "Harvard Annals," of "Lines in Classes B to B9A" in which the 3995 line is indicated as 'not' occurring in B5, B8, and B9 types (the type-stars for which are respectively φ Velorum, γ Gruis, and λ Centauri), it seems curious that Miss Payne describes it as having its maximum at B5, and as being last seen at A0. It would be interesting to know in which particular spectra of B5 and A0 types respectively the 3995 line fits her statement. Any worker amongst stellar spectra knows that those attributed to a particular type do not always show exactly identical spectra, but it seems almost incredible that two spectra could be allocated to the same sub-division of a group, one showing a certain line at its maximum for the range throughout which it occurs in the stellar sequence, and the other showing no trace of the line at all, without either of them being denoted as 'peculiar.'

Of the spectra available here, 3995 is certainly strongest in γ Orionis, the Harvard type-star for B2.

Cambridge University, March 7.

The "Gas Laws" in Surface Solutions.

M. ANDRÉ MARCELIN, in a recent paper (*Annales de Physique*, vol. 4, p. 459, 1925) referred to in NATURE of February 13, p. 247, states that the relation between the surface pressure F and area A is, with certain films, of the form of Boyle's law, $FA = kT$; but he states that k is much smaller than the universal gas constant.

Both kinetic and thermodynamic theory predict that at extreme dilution of the films, when the molecules are so far apart that their size and mutual cohesion become negligible, the product FA should be equal to RT, R having the same value of $1{\cdot}372 \times 10^{-16}$ (in c.g.s. units per *molecule*) as in a gas or a perfect solution. If k is much smaller for surface solutions than R, either there must be a great degree of association among the film molecules, or the thermodynamic theory is wrong. M. Marcelin's figures would require an association factor of about 18 for oleic acid on distilled water, and of about 60 for benzyl benzoate. He rejects this as improbable, but suggests an alternative explanation which seems quite impossible; he suggests that owing to movements of the film molecules perpendicular to the surface, a large proportion of them are so far out of the plane of the confining barrier that they do not exert pressure on it. But if they do not exert pressure on the barrier, they must be quite free to pass this barrier; if this is so the number of molecules in the film will be unknown, and the experimental method breaks down altogether.

We find, however, that in the region of pressures and areas covered by M. Marcelin's experiments, the relation between pressure and area is quite different from that reported by him. Our own recently published work (*Proc. Roy. Soc.* A, vol. 110, p. 423, 1926) shows that at low pressures the product FA approaches the theoretical value of $1{\cdot}372\ T$ (areas measured in sq. Å.U. per molecule). At higher pressures the course of the F-A isothermals followed very closely the isothermals for carbon dioxide in the region of the critical point, and indicated the presence in two dimensions of phenomena analogous to evaporation from a liquid film to a gaseous film. There was not, with any one of the compounds, which belonged to four different homologous series, any evidence of considerable association of the molecules before condensation set in. There was a general resemblance between the results on the different series, which indicated that the results are typical of all films. It was possible, however, that the two films on which M. Marcelin worked were exceptions to what we thought was a general law.

We have therefore examined the films of oleic acid on distilled water, and of benzyl benzoate. Benzyl benzoate gave such an unstable film that the surface pressures were evanescent and very small, vanishing almost entirely in about 4 minutes. We think the low pressures in this case are due simply to the molecules not remaining in the film.

With oleic acid, we find the film to be 'expanded' above about 0·2 dynes per cm., when it has an area of 49·7 sq. Å.U. per molecule. There is a fairly abrupt transition from this state into one at which the pressure is constant at about 0·08 dynes per cm., the 'vapour pressure' region. The substance thus behaves very much like the other fatty acids described in our recent paper. Recalculating the results given by M. Marcelin to sq. Å.U. per molecule as unit of area, there is little correspondence; the angle between the vapour pressure region in the F-A curves, and the much steeper 'expanded' curve is obliterated in M. Marcelin's results.

In the following table the results are compared:

Surface Pressure (dynes per cm.).	Areas per Molecule (sq. Å.U.).	
	Marcelin.	Adam and Jessop.
0·5	45	49·5
0·2	112	49·7
0·1	about 230	51·4
0·08	about 300	55 to 660, and probably upwards

The discrepancy is difficult to explain. We feel confident of our results, as the oleic acid was a particularly pure specimen given us by Prof. Lapworth, and the experimental results correspond so well with those of the other acids in our paper; moreover, our results are in accordance with a reasonable theory, which has been recently shown by Schofield and Rideal to include the slightly soluble fatty acids of the saturated series. It is exceedingly difficult to obtain oleic acid absolutely pure; we do not claim that our specimen was perfectly pure, as it probably contained a little palmitic acid. But it may be that M. Marcelin's oleic acid contained some impurity which would obscure the true course of the F-A curve just in this region. If this is so, it is a pure accident that he found the relation $FA = \text{constant}$.

We would also criticise M. Marcelin's experimental method, for his methods of cleaning the surface and handling the films do not seem adequate for quantitative work, with the very sensitive pressure-recording instrument which he describes. In the sensitive apparatus, he describes the float, which bounds one end of the film, as separated from the fixed side boundaries by channels about 1 mm. wide. In our experience even much smaller leaks would be fatal to accuracy, and we close this gap completely, with flexible metal ribbon. Leaks and accidental contamination are serious sources of error in this work, and too great care cannot be taken to discover and avoid these complications.

Origin of the Fresh-water Fishes of New Zealand.

IN the *Journal of the Linnean Society*, Zoology, 47, No. 313, pp. 99-140, 1925, Oliver has outlined what is virtually a new theory to account for the distribution of South Pacific plants and animals. It is of interest to note that the fresh-water fishes of New Zealand, not included in the above paper, appear all to conform with the suggestions: (1) Their present habits and nature are such that they may easily have crossed small areas of ocean and independent species originated in the separate land masses; or (2) marine species of a restricted habitat have taken to a life in fresh water, changing in form to meet the new conditions. Almost simultaneously Oliver (p. 109) and Skottsberg (*Bishop Museum Bull.* 16, p. 22, 1925) have independently suggested the modification of species and increase in number of forms after arriving at a new region.

Before the introduction of salmon and trout, New Zealand rivers swarmed with species of Galaxias, Anguilla, and other comparatively small fishes, of which the following is a complete list: *Geotria saccifera* Regan, *Geotria australis* Gray, *Anguilla aucklandii* Richardson, *Anguilla australis* Richardson, *Anguilla schmidtii* Phillipps, *Anguilla waitei* Phillipps, *Cheimarrichthys forsteri* Haast, *Gobiomorphus gobioides* (Cuv. and Val.), *Rhombosolea retiaria* Hutton, *Galaxias attenuatus* (Jenyns), *Galaxias fasciatus* Gray, *Galaxias brevipinnis* Günther, *Galaxias huttoni* Regan, *Galaxias kokopu* Clarke, *Galaxias lynx* Hutton, *Galaxias postvectis* Clarke, *Galaxias alepidotus* (Block and Schn.), *Galaxias burrowsius* Phillipps, *Neochanna apoda* Gunther, *Prototroctes oxyrhynchus* Günther, and *Retropinna retropinna* (Richardson).

Oliver suggests that among fish the Galaxiidæ and Geotridæ with headquarters in New Zealand owe their development and distribution to the New Zealand continent, which in former times stretched towards Antarctica. While it is by no means a proved fact that the headquarters of these families were in New Zealand in the Cretaceous period, present conditions would appear to indicate that such may have been the case. Much further investigation of the Geotridæ is required, but in the meantime it seems advisable, from facts I have gathered in regard to growth-changes in the life-history, to admit only two species in New Zealand. These species, *australis* and *saccifera*, are also known from Australia and Chile; but, as the Geotridæ in our rivers are essentially sea-going forms, they may be discarded, together with the Anguillidæ, as offering evidence either in favour of or against former land connexions.

The Galaxiidæ as a family are worthy of mention in that in New Zealand the highest development and the lowest degeneration of the family have taken place. Eleven members of the family are known in New Zealand fresh waters, the young of *Galaxias attenuatus* running from the estuaries of rivers in the spring months and forming the chief constituent of the southern white-bait. Though this species is found both in Australia and South America, it appears to be not nearly so prolific in those countries. Thus, it is quite possible that, in the Cretaceous period, when the New Zealand area was much greater, the Galaxiidæ, which had originated here, then spread to adjoining land masses. The degenerate members of the family are *Galaxias burrowsius* and *Neochanna apoda*, the former having almost lost the use of the ventral fin, while in the latter it has quite disappeared. These fish both hibernate during dry weather and are peculiar to New Zealand.

Gobiomorphus, represented by one species common in all New Zealand fresh waters, has numerous allies among the small Gobiidæ in rock pools on the seacoast. It is almost certainly a descendant of a coastal goby which has taken to a life in fresh water. Turning to Cheirmarrichthys, we note a relative in *Parapercis colias*, the common blue cod of New Zealand; so we may conclude that this species also has arisen independently in the New Zealand area. *Rhombosolea retiaria*, the river flounder, is common in estuaries of large rivers, and on one occasion I have examined an example taken by a trawler in Hawke Bay, New Zealand. There are three common marine species of Rhombosolea around our coasts.

Two species remain to be noted. These are *Prototroctes oxyrhynchus* (the New Zealand grayling) and *Retropinna retropinna* (the New Zealand smelt), each of which is allied to the Salmonidæ of the northern hemisphere, being the only fishes indigenous to New Zealand having an adipose dorsal fin. It is not necessary to erect a continent to explain either of these species; but, as a species of Prototroctes and a species of Retropinna are known in Australian fresh water and not in the sea, it is important that the representatives of Prototroctes and Retropinna in New Zealand rivers enter brackish water, as noted by me in the *New Zealand Journal of Science and Technology* (vol. 6, pp. 115 and 166, 1923). It has never been proved that either of these species has entered the sea. Possibly both Prototroctes and Retropinna originated in the New Zealand area and spread from here to outlying lands. Both species appear to spawn in brackish water, and it is quite possible that the young were formerly capable of crossing short oceanic areas.

The Nomenclature of the Banded Constituents of Coal.

IN view of the wide acceptance in Great Britain of the terms vitrain, clarain, durain, and fusain devised by Dr. Stopes to describe the banded constituents of British bituminous coal, and the introduction of the further terms anthraxylon and attritus by Dr. R. Thiessen, it may be of interest to define the relation between them. At a recent symposium of the Coal Research Club, at which both Dr Stopes and Dr. Thiessen were present, it appeared to be agreed that the two systems have entirely different bases and that each has its validity and use. It was the important service of Dr. Stopes (*Proc. Roy. Soc.*, 1919) to replace the vague terms bright and dull coal by others capable of exact definition. The basis of her system is a lithological one. There are two kinds of bright coal Vitrain is not in itself banded, and has a glassy lustre and conchoidal fracture. Clarain is inherently banded or striated, and consequently scatters light, and has a silky lustre, and does not break with a conchoidal fracture. These purely lithological characters are sufficient to define the terms, without resort to the microscope, a feature essential for practical purposes to retain. Dr. Stopes correlated them with the microscopic and chemical characters, but these are under further investigation.

Clarain, whether derived from a single plant fragment or from general debris, always shows marked structure in thin sections In vitrain the structure, even if not entirely absent, is relatively obscured or obliterated, so that it produces no striation or scattering of light at the surface. Dr. Thiessen's terms, on the other hand, have a botanical, not a lithological basis. It is the contention, first advanced by White and Thiessen in 1913, that the bright laminæ of coal (which from their description must have been vitrain) are always derived from parts of stems and roots. This material Thiessen calls *anthraxylon*. The term suggests 'coal derived from wood.'

Dr. Thiessen perhaps underestimated the contribution of cortical tissues to coal. Miss M. Evans, at the University of Sheffield, has found much vitrain to consist of periderm, and I have under investigation a thick band of clarain consisting wholly of the periderm of a Sigillaria or Lepidodendron. Nevertheless, it is clear that Dr. Thiessen includes in anthraxylon all the associated tissues of stems and roots His generalisation may be expressed in the statement 'all vitrain is anthraxylon.' The converse is not true: all anthraxylon is not vitrain; it may be clarain or even fusain, which Dr. Thiessen describes as 'carbonised anthraxylon.' Nothing could better illustrate the difference between the two systems of nomenclature.

In striking contrast to anthraxylon is the general plant debris, called by Dr. Thiessen attritus. The essential point is that whereas anthraxylon is of homogeneous botanical origin in stems and roots, attritus is of heterogeneous origin in plant debris of all kinds. It is a sort of concrete in which larger fragments (anthraxylon, spore-exines, cuticles, etc.) are embedded in a cement of finely comminuted debris. If the brighter components preponderate, it will be clarain; if the duller ones, it will be durain. The relation between the two systems may be tabulated as follows:

A. ANTHRAXYLON (of homogeneous botanical origin from stems or roots).	A_1 Structure absent, obscured or faint.	Lustre glassy, fracture conchoidal or semi-conchoidal, not laminated.	VITRAIN
	A_2 Structure well preserved.	A_2 I Dull, friable.	FUSAIN.
		A_2 II. Lustre silky, minutely laminated.	CLARAIN.
B. ATTRITUS (of heterogeneous botanical origin, general plant debris).	B_1 Much anthraxylon present.	Lustre silky, minutely laminated	CLARAIN.
	B_2 Little anthraxylon present.	Dull, compact.	DURAIN.

Should it prove that there is a vitrain not derived immediately from portions of stems or roots, this will simply mean that there is a kind of vitrain not contemplated by Dr. Thiessen. The two kinds of clarain could be distinguished as anthraxylous and attrital clarain respectively. Dr. Thiessen uses the adjective 'attritious,' but I do not think it happily formed, and consider 'attrital,' on the model of detrital, to be better.

The Action of Strychnine on the Cerebellar Cortex.

THAT strychnine has a stimulating action on the cerebellar cortex was shown by me a few years ago—(*Science*, 51, 413, 1920). On the application of strychnine to the surface of the *lobulus ansiformis* or cerebellar hemisphere the motor manifestations consist in increased tonus, together with clonus, affecting particularly the ipsilateral hindleg, though affecting also, to some extent, the forelegs and the contralateral hindleg. My positive results obtained with strychnine in the cat agree with those of Shimazono (*Arch. f. mik. Anat.*, 80, 397, 1912), who observed an ipsilateral increase of tonus after applying strychnine to the cerebellar cortex in the pigeon.

It becomes a matter of interest to determine the action of strychnine when applied to the surface of the *lobus anterior*, from which, as Sherrington showed, faradisation yields inhibition of decerebrate rigidity. I have observed that the application of strychnine to this surface results at times in remarkable phenomena: in one instance, the animal (cat) having been decerebrated under ether with the Sherrington decerebrator, 1 per cent. strychnine was applied to the surface of the *lobus anterior*. This quickly resulted in two motor pictures, which alternated regularly: (1) Head and neck dorsiflexed, movements of progression in shoulders, the forelegs being stiffly extended, movements of progression in hindlegs; (2) head, neck, and body flexed ventrally, the hindlegs in violent extension and the forelegs in extension of somewhat less degree. At other times the action of the strychnine on the *lobus anterior* is manifested simply by a heightened intensity of the decerebrate tonus.

A question which obviously demands an answer is whether the application of strychnine to the *lobus anterior* changes in any way the inhibition of decerebrate rigidity elicitable by faradisation of this surface. Bremer (*Arch. int. de Physiol.*, 25, 131, 1925) has already shown that the intravenous injection of strychnine does not modify the inhibitory response.

In my experiments the cat was decerebrated under ether with the decerebrator, and faradisation with bipolar electrodes was applied to the *lobus anterior*. There resulted the typical inhibition of the tonus in the forelegs; 1 per cent. strychnine nitrate was then applied; this resulted in some increase in the tonus of the forelegs. On repeating the faradisation, inhibition of the tonus was again evoked, the effect being, however, slightly less pronounced than before the application of the strychnine; then followed an augmented tonus (rebound), which was greater than before the application of the strychnine. These observations were repeated a number of times after several applications of strychnine and always with the same result.

Clearly we must conclude that strychnine applied to the cortex of the *lobus anterior* does not reverse, though it reduces slightly, the inhibitory response which can be elicited therefrom; the subsequent rebound is somewhat enhanced, a modification of the same kind as that noted by Bremer after intravenous injection of strychnine. The question as to why strychnine, though apparently exciting the cortex of the *lobus anterior*, should evoke an augmented instead of a diminished tonus, as does faradisation, remains for the present undecided.

The Relationship between Viscosity of the Blood and Shock.

IN a series of experiments in which solutions of peptone or histamine were injected intravenously into rabbits I have observed that, accompanying the fall in blood-pressure and other anaphylactoid phenomena, there is a marked reduction in the viscosity of the blood. I consider that this lessened viscosity is the primary cause of the fall in blood-pressure and the accompanying symptoms of shock. That a fall in blood-pressure can be produced by a reduction in the viscosity of the blood was proved by Bayliss (*Proc Roy. Soc.*, 89, 380, 1917), who proved that on bleeding an animal and afterwards injecting a corresponding amount of saline, both blood-pressure and viscosity show parallel reductions.

In my experiments, rabbits were anæsthetised with ether and urethane. Blood-pressure was recorded from the carotid artery and samples of blood were drawn from the femoral artery before injection of the peptone or histamine, and at intervals following the injection. The viscosity of these samples was determined by a viscosimeter of the Oswald type, the temperature being kept constant during the observations. The peptone or histamine, dissolved in physiological saline, was injected into the external jugular vein.

Following the injections, an immediate fall in blood-pressure was observed and the animal showed symptoms of shock. Examination of the blood showed that the viscosity was diminished. As a control, the experiments were repeated, with the difference that the peptone or histamine was dissolved in saline gum acacia solution of the same viscosity as blood; while the decrease in viscosity following these injections was not quite so great as in the former experiments, it was nevertheless very marked.

It seems plausible, then, to conclude that the fall in viscosity is produced by the peptone or histamine *per se* and not by the small amount of solvent in which it is dissolved. In conclusion, I wish to express the view that the anaphylactoid phenomena observed following the injection of peptone or histamine owe their origin primarily to the lessened viscosity of the blood and the resultant diminution in blood-pressure which are induced by the injections of these substances.

Viscosity determinations of the blood of sensitised guinea-pigs before and after injections of the provocative dose are now being carried out. The results indicate a definite decrease in viscosity following the injections.

Domestic Heating.

IN her letter in NATURE of March 6, p. 343, Dr. Stopes affords no evidence that the beneficial effects which she says she derived from the glowing coal fire were due to coal. She might have got equally good effects from a *glowing* coke fire, gas fire, or electric heater. She compares the effect of lying naked in front of a glowing coal fire with stripping in a warm room. Advantage lies in the use of a visible source of radiation.

This winter's experience has shown us that the close-up use of electric lamps in the Zoo has made a great difference to the marmosets, iguanas, etc. Dark heat does not suffice to keep such animals alive. We, and they, need visible rays which penetrate to, and are absorbed in, the blood beneath the epidermis, the red rays penetrating still deeper, and ultra-violet rays, which are absorbed in the epidermis, the energy of all these rays being converted in living cells. Dark heat is absorbed by the water in the surface layer of the body—quite another thing. While there is no evidence of any mysterious health-giving property in a coal fire, such as Dr. Stopes imagines, by polluting the atmosphere it causes great economic loss, and by screening off sunshine lessens health and happiness. We should therefore take to smokeless fuels, keeping to visible sources of radiation which are not only healthy but also adaptable to our changeable climate.

LEONARD HILL.

Chemical Society Publications Fund.

IT is a welcome sign that research work in chemistry emanating from our universities continues steadily to increase. Pessimists told us that the increase which followed the War was due to abnormal conditions and that the apex of the curve would soon be reached. Fortunately for our chemical well-being, this is not the case and the curve continues to rise. Unfortunately, the costs of printing do not diminish and the financial burden on publishing societies continues to grow.

In order to ease the burden, the Chemical Society has raised a Publications Fund which, through the generosity of fellows of the Society and chemical manufacturers, now approaches 5000*l.*; but the income from this is still too small to be really effective.

The Society acts as a publishing body for the universities, and does so freely in the interests of chemical science. Nevertheless, it is gratifying to record that one university, namely, that of Birmingham, by subscribing 100*l.* from its research fund to the Publications Fund, has recognised the work the Society is doing for it and for academic institutions in general. *Venienti occurrite morbo.*

The Modern Boiler-House.

By Eng.-Capt. Edgar C. Smith, O.B.E., R.N.

FEW departments of engineering practice have seen more radical changes than that of steam raising. Stokeholds of ships and power stations have been transformed. Where dirt, confusion, and inefficiency often reigned there is now order and method, and brawn and muscle have made room for skill and trained intelligence. Science has come into its own, and the modern boiler-room reflects the progress of the time. Installed in well-lighted and spacious buildings, the boilers and all their accessories are the objects of the care of the engineer-in-charge as much as the main machinery itself. Water-tube boilers, super-heaters, economisers, air heaters, mechanical stokers, pulverised fuel systems, forced and induced draught fans of many types have taken the place of tank boilers fired by hand, while new forms of gauges and indicators keep continuous records of the fuel consumed, the analyses of the gases, the temperatures of gases, steam, and water, and, in some instances, steam-flow meters are fitted which make the approximate test of a boiler a comparatively simple matter.

The most advanced boiler practice is to be found in the electric power stations. Of such stations there are in Great Britain nearly six hundred concerned with the public supply of electric current, but the majority of them are small. Those at Barking, Manchester, Birmingham, Glasgow, Newcastle, and a few others are of considerable size; but it is in the United States we see the rise of the so-called super-power station—a super-power station being essentially a very large plant comprising a part of a regional system wherein the more efficient plants are linked up. Electricity is used in America to a far greater extent than in the old world, and as much current is generated in the United States as in all the countries of Europe combined. Some striking figures and diagrams regarding the electrical industry is given in the January issue of the *Electrical World*, where it is stated that the power distributed in the United States last year amounted to 54,413,000,000 kilowatt hours, the corresponding figure for Great Britain being 6,681,000,000 kilowatt hours. Other interesting details regarding the super-power stations were also recently given by Mr. W. H. Patchell in his honorary members' lecture to the Junior Institution of Engineers. Mr. Patchell has himself been connected with power station work for the last forty years, and he was the pioneer of the very large boiler.

Modern power station boilers are invariably of the water-tube type, among the most popular being the Babcock and Wilcox and the Stirling. Pressures in such boilers have gradually advanced until to-day 300 lb. and 400 lb. per square inch is common, while there are stations using steam at 500 lb., 600 lb., 800 lb., and even 1200 lb. pressure. Boilers are also made in very large units. Copper, brass, wrought iron and steel have all been used for boiler tubes, which formerly were made from sheets rolled and welded; but thanks to the invention of the German metallurgist, Mannesmann, boiler tubes now are of solid drawn steel, and with such tubes failures are infrequent.

The stoking of the boilers is done by one of two types of mechanical stokers known as chain-grate stokers and under-feed stokers, or the coal is pulverised and blown into the furnace by jets of air. In chain-grate stokers the coal is fed from a hopper on to an endless chain of short fire-bars linked together, the grate travelling slowly into the furnace at about 2 to 6 inches per minute. With such stokers, firebrick arches are employed to reflect the heat from the fire and assist the combustion of the gases. The ash falls off the chain grate at the back of the furnace and is conveyed away by various means. The size of a large chain grate may exceed 20 feet square. In an under-feed stoker the coal is fed into the furnace by retorts and is thrust up under the already burning coal, the fuel being agitated by reciprocating fire-bars. Thick fires are the practice with under-feed stokers. Many types of mechanical stokers are in the market, and the choice is determined largely by the class of coal to be burned.

The most interesting development in boiler firing is the comparatively new system of using coal dust. In this case the coal is crushed, then passed through a magnetic separator to remove pieces of stray iron, and, after being dried in steam or hot-gas driers, is pulverised in mills to such a fineness that most of it will pass through a sieve with a mesh of $\frac{1}{100}$ of an inch. From the mill it is conveyed to bunkers, from which it is delivered to the burners. In a plant using pulverised fuel the lower drum of the boiler may be some 20 feet or more above the ground floor, the walled-in space beneath the boiler constituting the furnace or combustion chamber. So large are some of these combustion chambers that it would be possible to place a two-storeyed double-fronted villa in one of them. The coal dust is injected into the chamber through nozzles pointing downwards from a position corresponding to the cornice of a ceiling. The very high temperatures reached have called for improvements in refractory materials for the walls of the combustion chambers, but a promising experiment has been made by forming the walls of water-tubes with longitudinal fins welded on them. With pulverised fuel the ash falls as minute drops of liquid slag. A screen of water-pipes placed about a foot apart across the bottom of the combustion chamber cools these drops, and the ash reaches the floor as fine dust, which is easily dealt with.

An integral part of every modern boiler is the super-heater through which the steam passes on its way to the engine. Super-heating is now in use in ships and locomotives as well as in power stations, and there is a rough rule that 10° F. super-heat leads to an economy of 1 per cent. in the fuel.

After the gases have passed among the boiler and super-heater tubes they are still at a moderately high temperature, and are therefore caused to flow through an economiser for heating the feed water and through a pre-heater for heating the air for the furnaces. Finally, at the top of the boiler-house, they are drawn into the induced draught fan and ejected into the chimney-stack.

A modern boiler-house is a steel-framed structure of three or four storeys, perhaps 100 feet in height. Platforms at intervals support the various sections of the plant, and gratings and ladders give access to the stop-valves, gauges, burners, and other fittings. Roomy and well lighted inside, the buildings are designed by architects especially qualified in such work, and the exteriors are both pleasing and appropriate.

Super-power stations each designed for an ultimate capacity of over 300,000 kilowatts, have already been erected at St. Louis, Chicago, Pittsburg, New York, Brooklyn, Detroit, Boston, Cincinatti, and one or two other places, and a few particulars of some of their boiler plants may be of interest.

What will probably be the largest station is the Crawford Avenue station of the Commonwealth Edison Co., Chicago, and it was for this station Messrs. C. A. Parsons and Co. constructed the fine 50,000 kilowatt turbo-generator, the model of which was shown at the British Empire Exhibition at Wembley, from whence it was removed to the Science Museum, South Kensington. A full description of this set is in *Engineering* for March 5. The ultimate capacity of Crawford Avenue will probably reach 800,000 kilowatts. Very large Babcock and Wilcox boilers are installed, the tubes being 15 feet long, while the steam drums are 4 feet in diameter and 32 feet long. The drums are of steel plates 1⅞ inch thick, and the riveting is of an exceptional character. Forced draught chain grates are used, the grates being 24 feet wide and 20½ feet long. Steam is generated at 600 lb. pressure and delivered to the turbines at 550 lb. pressure at a temperature of 725°. About 190 tons of steam per hour is required for the single 50,000 kilowatt Parsons set. The boiler-house also contains a reheat boiler through which the steam is caused to pass on its way from the H.P. turbine to the I.P. turbine. The steam leaves the H.P. turbine at 100 lb. pressure and at a temperature of 425° F., and enters the I.P. turbine at about the same pressure but with its temperature increased to 700° F. Economisers are used, but the feed water, before entering the economiser, has already passed through five steam heaters, with the result that it enters the economiser at 315° F. and leaves at 380° F. At Crawford Avenue full advantage is made of the modern system of 'bleeding' the turbine.

Another large plant is that of the Detroit Edison Co., which supplies electricity over a very large area and sells it to the farmer 50 miles away at the same price as to the town dweller. The company has stations at Delray, Connor's Creek, and Marysville, and a new station has recently been erected at Trenton Channel. The Stirling boilers here work at 410 lb. pressure and the steam is super-heated to 700° F. Pulverised fuel is used entirely. A section of the boiler-house shows the ash-shoot at the ground level, the boiler floor 45 feet above this, and the roof 130 feet from the ground. Standing in the huge combustion chambers, the ash-shoots are at one's feet while the boiler tubes are some 50 feet overhead. The volume of such a combustion chamber is about 25,000 cubic feet, and one boiler will supply sufficient steam for a 25,000 kilowatt machine. At present there are three 50,000 kilowatt turbo-generators installed. Electricity is generated at 12,000 volts and distributed by overhead mains at 120,000 volts.

With the reputation of having established a record in economy, the Philo Station at Zanesville, Ohio, is a station possessing many remarkable features. It forms one of the plants of the American Gas and Electric Co., and was designed "to produce a marketable commodity at the lowest possible price." The thermal efficiency of the plant worked out at 23·81 per cent. The boiler pressure is 650 lb. and the steam temperature 750° F. In addition to the main boilers there are super-heaters, economisers, air heaters, forced and induced draught fans, and a reheat boiler as at Crawford Avenue. This station is unique in that it is able to draw its circulating water for the condensers from a reservoir at a higher level than the machinery, and for ten months in the year, therefore, no circulating pumps are required. Philo is but a link in a great system supplying electricity to parts of Ohio, Indiana, Pennsylvania, and West Virginia.

All records of boiler pressures in actual use are surpassed by the 1200 lb. pressure generated in the remarkable Babcock and Wilcox boilers at Calumet and at the Edgar station, Boston. At Boston three large boilers provide the main steam supply at 350 lb. pressure, but there is a separate boiler working at 1200 lb. pressure. This very high pressure steam is first used in a 2500 kilowatt turbo-generator, from which it exhausts to a reheater and then finds its way into the 350 lb. main of the station. The steam drum of the 1200 lb. boiler is an exceptionally fine piece of work. It was made from a steel ingot weighing about 100 tons. The ingot was 'upset' until about 8 feet in diameter, a core of 23 inches was then removed from it, and by subsequent operations the ingot was drawn out into a drum 34 feet long and 4 feet in diameter, the walls of which were 4 inches thick. Such work is within the capacity of only a few firms, but it well illustrates the demands made on the manufacturer by the designer of modern boilers.

Trends in American Geology.

In an address delivered to Section E (Geology and Geography) at the recent meeting of the American Association for the Advancement of Science, Dr. W. C. Mendenhall dealt with "Some Recent Trends in American Geology," indicating the lines along which, according to his view of the matter, effective progress in the science of geology is being made. Modern science, said Dr. Mendenhall in his opening remarks, is too broad and too complex to be comprehended by any individual, and any one of the sciences is beyond the grasp of one man. "Progress is made by the specialist or group of specialists who devote themselves to a limited field. Presently there comes out of their endeavours a generalisation which can be used by other groups. Thus the advances in different fields are linked together and a united front is maintained."

Study of Sediments.

A promising development of the last few years is the revival of interest in the petrology of sediments and the organised attack that is being made on the problems connected therewith. The United States National

Research Council has appointed a Committee on Sedimentation under the chairmanship of Drs. Vaughan and Twenhofel. Under the guidance of this committee it is proposed to issue a treatise on sedimentation for the purpose of directing attention to the research problems involved. Laboratories for the study of sediments are being installed in various institutions, and new courses are being organised in several of the universities. Already, scientific papers are being published on this subject, and petrographers are ceasing to find their sole interest in igneous problems. It is expected that the influx of new data arising from these investigations will have much influence on the study of palæogeography by throwing new light on the climatic and other conditions under which sedimentary rocks have been formed.

GLACIAL HISTORY.

Two conspicuous tendencies are displayed in this branch of study; one towards the establishment of a more definite chronology in glacial events, the other towards linking up these glacial events more closely with pre-glacial history. In this connexion perhaps the most striking and best-known quantitative attack is that of Dr. Antevs, who, with the assistance of the Canadian Survey, Harvard University, and the Carnegie Institution of Washington, is applying the methods of Baron de Geer to North American problems.

STRATIGRAPHY AND PALÆONTOLOGY.

In these departments there has been a large increase in the amount of available data, which has been collected by more refined and exact methods, and on that account has made possible more definite correlations and more exact interpretations of the physical environment in which strata have been formed. In the light of this newer data, old problems like that of the Laramie problem are vanishing, and strata, the ages of which have long been considered doubtful, are taking their places in the normal sequence. Ulrich has recognised in America two large and extensively developed assemblages of Lower Palæozoic rocks which he thinks deserve to rank as systems, although they are but meagrely represented in the classical localities of north-western Europe. Much progress is being made in the study of the smaller fossils, especially in oilfield stratigraphy, and the research now being carried on in this connexion is expected to lead to interesting results and useful developments in the near future.

PETROLEUM GEOLOGY.

The last decade has witnessed a large absorption of geological talent by various oil interests, consequent upon recognition by the latter of the fact that the science of geology is an essential weapon in the attack on problems of oilfield exploration and development. This has led to a rapid development of the more obviously favourable areas. The exploration of less favourable areas requires more refined methods, in the application of which the more alert organisations are engaging physicists, chemists, palæontologists, and more geologists in order to cope with the difficulties involved in the maintenance of supplies of oil.

The solution of the problem of the distribution of petroleum in the earth is one involving many hindrances and difficulties. In spite of the excellent forum offered by the American Association of Petroleum Geologists and its journal, there is not complete freedom in the interchange of ideas, owing to the fact that some companies hesitate to give the world the full benefit of results which they have been able to obtain only at much expense. There is, moreover, the further difficulty that any particular company or group is often hindered by commercial considerations from taking a large view of the research aspects of the problems it has to deal with. It is hoped, however, that oil companies will soon come to realise more fully how much might be done for the advancement of knowledge by exploiting more fully the opportunities that already exist. Leaders among petroleum geologists are fully aware of these opportunities, and their co-operation, on one hand with the oil-company executives, and on the other with various non-commercial scientific organisations, is expected to have fruitful results. The American Petroleum Institute recently announced that John D. Rockefeller had provided a fund for petroleum research. It seems likely, therefore, that the next decade will see large advances in knowledge concerning the origin of petroleum and the extent of the United States petroleum resources.

ORIGIN OF COAL.

The results of a combined attack by geological, chemical, and physical methods upon the problems of the origin and classification of coal has tended in recent years to confirm the old belief that coals of different kinds have a common origin, and that they represent different stages in the metamorphism of peat, material differences among coals being due to differences in the nature and relative amounts of the various original plant-debris constituents. A notable outcome of these researches into progressive carbonisation has been its use by Dr. D. White as an indicator of the extent to which the beginnings of metamorphism in rocks has gone, and the practical application of this indicator in determining areas in which the survival of liquid and gaseous hydrocarbons may be expected. Research is now being undertaken to ascertain whether a study of carbonaceous sediments other than coal can be turned to similar account, so that in the absence of coals it may still be possible to predict whether any petroleum that formerly may have been present in a region has survived.

SEISMOLOGY.

In this field of work, a co-ordinated effort is being made by the Seismological Society, the Carnegie Institution of Washington, the Research Council, the Coast Survey, the Geological Survey, and many universities and individuals, to collect facts from which it may be possible to define seismic and non-seismic areas, and to classify the former according to their degree of seismicity. The aim of this work is to ascertain how far it may be possible to predict the immanence and locus of earthquake shocks, so as to be prepared in some measure for their occurrence. This work will derive stimulus and support from business interests. Already it is a broad business problem, the approach being mainly from the point of view of insurance.

Ore Deposits.

For a generation or so, according to Dr. Mendenhall, this branch of geology has brought forth no such universally accepted generalisation as appeared in the preceding period. A large amount of data has been accumulated, however, and the possibility of interpreting these data by scientific principles has been actively tested for the purpose of solving the important economic problems of ore-finding and mine development. A growing consciousness of the prospective shortage in supply of the precious metals, as well as some of the base metals, has led to attempts to survey broadly the whole field of mineral supplies, to see whether, from the detailed studies that have been made already, any general laws can be deduced that will prove helpful as a guide to means of increased production. In this connexion there has been in recent years a growing appreciation of the international aspect of the problem of mineral supplies.

As Dr. Mendenhall fully realises, however, this, and other of the topics he deals with, relate to applied rather than to pure geology; and, unless one is satisfied that geology is a perfected science, it seems needful that the fundamental principles of the science should receive attention; for science has to be established before it can be applied. Is sufficient being done for the principles of geology by the present generation, and is adequate progress being made towards the unity and co-ordination of the various specialised branches of geology? Dr. Mendenhall assures us that the trends in American geology show that sound and substantial progress, impressive in the aggregate, is being made. His rather optimistic view of this matter is defined in his opening remarks, as already mentioned, to the effect that progress in the science as a whole is made by the maintenance of a united front by bands of specialists, each ploughing its rather lonely furrow. We may, however, reasonably doubt whether bands of specialists are capable of moving forward on a united front without some generalship in the way of fundamental scientific principles to guide them.

Looking at the subject from a less appreciative point of view, and presumably more as a student of principles than of details, President Lowell of Harvard said not long ago that for many years geology had taken no forward step. In his address last year as president of the Institution of Mining and Metallurgy, Sir Thomas Holland voiced a similar view. These differences of opinion as to whether geology is making progress clearly depend upon the viewpoint we take. Looking at the matter from a specialistic point of view, Dr. Mendenhall is no doubt right in claiming that there has been movement. Viewing it more generally, President Lowell is no doubt equally right in claiming that such movement as has taken place does not constitute progress. Anyhow, it seems desirable enough that geologists should keep well in mind the need that exists for the cultivation of scientific principles as well as specialistic details, for only by so doing will it ever become possible either to raise the status of geology as a science, or to cope with the many difficult problems, both scientific and economic, that await solution. T. C.

British Association at Oxford.

Preliminary Programme.

The preliminary programme of the British Association meeting in Oxford on August 4-11 has been issued from the office of the Association at Burlington House. It indicates that the presidential address by the Prince of Wales is expected to deal, among other matters, with relations between scientific research, the community, and the State, both at home and in the overseas Dominions. The address will be delivered, at 8.30 P.M. on August 4, in the Sheldonian Theatre, but as the accommodation there is not expected to suffice for so large a meeting, the proceedings will be relayed to the Town Hall, and, if necessary, to the Union Society's Hall or elsewhere.

The subjects of a number of the addresses by sectional presidents are announced. In the mathematical and physical section, Prof. A. Fowler will deal with the production and analysis of spectra; and spectroscopy is likely to be an important subject of discussion in this section. Prof. J. F. Thorpe will address the chemical section on the scope of organic chemistry, and Prof. S. H. Reynolds the geological section on progress in the study of the British Lower Carboniferous rocks. In the zoological section, Prof. J. Graham Kerr will speak on biology and the training of the citizen. The Hon. W. Ormsby-Gore will bring the first-hand experiences of his African tours to bear in discussing the economic development of British tropical Africa, in the geographical section. Sir Josiah Stamp will address the section of economics on inheritance as an economic factor. In the engineering section, Sir John Snell will deal with the recent and probable future development of the electricity supply. Prof. H. J. Fleure, in the chair of the anthropological section, will review the modern position in regard to knowledge of the evolution of human races; and Prof. J. B. Leathes, addressing the physiological section, will deal with function and design. Announcements received since the programme went to press include that of Sir Daniel Hall's address to the agricultural section; his subject will be the area of cultivation required to feed the population. Prof. F. O. Bower, who succeeds the late Dr. W. Bateson as president of the botanical section, will review the state of botanical science at the present time in comparison with that at the Oxford meetings in 1894 and 1860. One of the evening discourses will be given by Prof. A. S. Eddington, and a large number of discussions on leading scientific subjects have already been arranged. On Thursday, August 5, there will be two on important Imperial topics—educational training for life overseas, and the effect of contact with European civilisation upon African native races.

The Vice-Chancellor of the University of Oxford and the Mayor of Oxford will hold receptions, and the local executive committee will give a conversazione, with the co-operation of the Junior Scientific Club. A number of excursions to places of interest are also being arranged. Among preachers at the cathedral and principal churches on the Sunday during the meeting will be the Bishops of Oxford and Winchester, the Dean of St. Paul's, and the Master of the Temple, and at Mansfield College, Dr. Selbie, the principal. Assistance is offered by the local committee to members desirous of obtaining accommodation, during the meeting, in colleges, hostels, lodgings, and private hotels, and there should be no lack of room for visitors, provided (but the proviso is important) that early application be made on the form sent out with the programme.

News and Views.

WE note with pleasure the appointment of an engineer officer of the Royal Navy as a Naval A.D.C. to the King. This is the first time this honour has been bestowed upon a naval engineer. The officer selected is Engineer Captain E. P. St, John Benn, who is at present in command of the Royal Naval Engineering College, Keyham. The College, it will be remembered, was opened in 1880, but owing to the changes due to the Selborne scheme of training the direct entry of engineer cadets ceased and for some years the College was closed. It was reorganised in 1920 and midshipmen from Dartmouth and special entry cadets for the Engineering Branch now enter it for a four years' course of training in mechanical and electrical engineering. Captain Benn's appointment is the direct outcome of the representations made by the Engineering Institutions to which we have already referred, and to which the Duke of Northumberland alluded in his presidential address last week to the Institution of Naval Architects. In the course of his remarks the Duke of Northumberland said that in the opinion of the Institution it was an anachronism to emphasise the difference between the executive officer and his engineering colleague, and that it was felt that if a place could be found in the Board of Admiralty for direct representation of the engineering branch it would certainly tend to make engineers confident that their views would be fully considered. With these views we are in entire agreement

THE Hon. Robert Boyle remarked that "it may much assist us to take notice of the multitude of Effluvia, and make us expect great matters from them," and the chief conclusion reached in the course of some investigations recently undertaken for the *Forum*, and described by Mr. E. E. Free in the March issue of that journal, is: "that a conscious effort to train our national noses might have a distinctly worth-while effect on the comfort of living." A similar conclusion has been arrived at by quite a number of investigators; reference may be made to various papers on the subject listed in "Osmics" (Oliver and Boyd, Edinburgh, 1922, 1924). The conclusion is strengthened by finding that the percentage of correct identification of the odours used in these tests is only 21·2, and in a group of students at Dartmouth College, 37·4, whereas a trained pharmacist identified correctly eleven out of twelve odours submitted. The conclusion that people do not differ greatly in their olfactory acuity is somewhat vitiated by the circumstance that the paper does not reveal the employment of exact olfactometric methods, the odours being merely referred to as very weak, weak, moderately strong, and strong. While Henning's method of classifying odours is criticised, there is no mention of Zwaardemaker or Heyninx. "We found a complete absence of indication that any primary list exists at all. So far as we can determine from our tests each odour is smelled individually and all of them unlike each other." This conclusion may be due to the small number of odours employed, as well as to the circumstance that association by similarity involves more elaborate neuron patterns than association by contiguity. Various instances are given of affects and associations due to odours, and Mr. Free concludes that smells are largely recognised by their associations. The value of the paper would seem to lie in the plea for training the sense of smell, and perhaps, too, in emphasising the value of previous work on the subject, for example by Titchener, Vortriede, Harris, and others, not to mention Dr. Dan McKenzie's "Aromatics and the Soul," which Mr. Free would find to be an excellent introduction to the subject he has written about.

IF it can be shown that those who launch a new scientific journal are justified in their claim that it can indeed contribute to the welfare of the science that it is meant to serve, then even those who bemoan the increase of publications will welcome it. In the foreword to the first number of the *Quarterly Review of Biology*, Prof. Raymond Pearl, the editor, gives adequate reasons for adding yet another to the 25,000 already existing reputable scientific journals of the world. The new journal is addressed primarily to all men of science who wish to keep soundly orientated as to the general progress of biology, but it is intended further to be an effective answer to the menace of Fundamentalism, which is best met by the diffusion of scientific knowledge among intelligent men and women who are not professionally scientific workers but are genuinely interested in the advances that are being made. The journal, which costs 5·50 dollars a year, is published by the Williams and Wilkins Company, Baltimore; the associate editor is Prof. R. W. Hegner, and the advisory board includes fifteen of the best-known American biologists, most 'specialisms' being represented. The first number includes the following papers: "The Biology of the Mammalian Testis and Scrotum," by C. R. Moore; "Symbiosis among Animals," by L. R. Cleveland; "Experimental Studies on Morphogenesis in the Nervous System," by S. R. Detwiler; "A Review of the Discovery of Photoperiodism," by K. F. Kellerman; "Recent Discoveries in the Biology of Amœba," by A. A. Schaeffer; reviews of seventy-seven new biological books, including a long critical one, by J. H. Gerould, of Cuénot's "L'adaptation." The articles are written by acknowledged authorities capable of presenting accurate, balanced, and critical summaries of the present position of their own particular fields. The list of papers to appear in future numbers is such as would seem to indicate that the success of this new journal is assured. It is but fitting that Prof. Raymond Pearl, who by his outstanding ability and almost superhuman energy has, in the past, set such a pace in biological research that few of us could keep up with him, should, by producing the *Quarterly Review of Biology*, enable us 'to get our second wind.'

THE Report for 1925 of the Marine Biological Station at Port Erin, Isle of Man, drawn up by Prof. Jas. Johnstone, shows a very satisfactory state of affairs and a large amount of work has been accomplished both by the resident staff and by occasional workers. The fish hatchery has yielded more than three million plaice larvæ which have been set free into the sea, and of the parent stock not one died, all being in good condition. More larval lobsters were reared than in any previous year. From fifteen lobsters 526 lobsterlings, fed on fresh plankton, were reared in jars, 500 of these being set free into the sea besides many thousand younger larvæ. The naturalist of the Laboratory, Mr. J. Ronald Bruce, has published an interesting paper on the "Salinity and Carbon Assimilations in Amphidinium" in the *British Journal of Experimental Biology*, and proposes further instalments of this important work on the metabolism of the shore-living dinoflagellates, which on the Port Erin sands offer special facilities for such studies. He is also investigating the seasonal variations of the gaseous metabolism in the common mussel. From the oceanographical department of the University of Liverpool, Mr. R. A. Fleming publishes "Notes on some Fish landed from the South-Western Hake Grounds," the fish, chiefly sharks, having been sent to the Laboratory for researches into their liver-oils, and Mr. R. J. Daniel describes a large and perfect Stenoteuthis measuring six feet including the tentacles, taken in the trawl off St. Kilda. Dr. Margery Knight, from the botany department of the University, reports on the investigations on Algæ undertaken by herself and pupils—research covering a wide area which promises to yield important results only obtainable by methodical team-work and keen workers both in the laboratory and on the sea-shore. The absence of a research boat at Port Erin is certainly to be deplored, and it is hoped that this gap will be filled at the earliest opportunity.

IN 1923 the Government of Finland issued invitations for a conference of delegates from the States which border the Baltic in order to discuss the desirability of common action whereby a chain of first order triangulation round the Baltic shores might be carried out. The conference met at Helsingfors at the end of June 1924, and was attended by representatives of Esthonia, Finland, Germany, Lettonia, Lithuania, Poland and Sweden. A report has now been issued (*Comptes Rendus des Séances de la Conférence Géodésique réunie à Helsingfors*, Helsinki, 1925). The discussions which took place were essentially of a technical character, and a number of resolutions were adopted with the view of ensuring the work being homogeneous, and of a uniformly high standard of accuracy in all portions of its circuit. A considerable portion of the chain is already in existence in various countries, but the additional extensions and connexions which will be required were discussed and agreed upon. In such new work the mean length of a side of a triangle is to be about 30 km. and no angle is to be less than 30°; heliotropes or lamps are to be used as signals except where the sides are short. The instrument recommended was a theodolite having divided circles of 20 cm. diameter and reading to 2″. Six additional bases are to be measured at various points of the chain with Jäderin wires which are to be verified by measurements made on a selected control base. Astronomical determinations of latitude, longitude, and azimuth are to be made as often as practicable, and it was agreed that Laplace stations should in any case be not more than 200 km. apart. Considerable emphasis was laid on the importance of gravity determinations, which are to be made as frequently as possible. Von Sterneck's pendulum apparatus is to be employed, and those used will be standardised at Potsdam. The publication not only summarises briefly the plans which have been made for carrying out this important piece of European geodesy, but it also furnishes a convenient abstract of the operations which have to be carried out in a piece of modern geodetic triangulation, and of the accuracy which is required at the various stages of the work

WE have received three volumes of the final report on the Japanese earthquake of 1923. They belong to the series of Reports of the Imperial Earthquake Investigation Committee printed in Japanese, and it is much to be hoped that before long they will appear in English in the corresponding series of Reports in Foreign Languages. If we may judge from the tables of contents and the numerous and admirable plates, the complete report on the earthquake will assuredly take its place as one of the finest accounts that we possess of any natural phenomenon. The first volume (No. 100, A) is mainly concerned with the earthquake in general and its after-shocks, and with the distribution of intensity in various districts; the second (No. 100, B) with the geology and physiography of the central area, the changes in the level of the land and of the floor of Sagami Bay, and the sea-waves following the earthquake; and the third (No. 100, E) with the great fires in Tokyo and other places. Among the plates may be specially mentioned the detailed chart showing the changes in the bed of Sagami Bay, the seismograms from Tokyo and elsewhere, the mareograms from many Japanese ports, and the map showing the isoseismal lines bounding places in which the percentage of collapsed houses reached 30 and 5, respectively. Yokohama lies within the former curve, and the greater part of Tokyo outside the latter.

The Weather Bureau of the U.S. Department of Agriculture has issued "Instructions to Marine Meteorological Observers" (W.B. No. 866). For ocean meteorology the Weather Bureau asks for one regular observation a day at noon, G.M.T. In certain designated areas from which observations are transmitted by radio-telegraphy, an additional regular observation is asked for at midnight, G.M.T. The reason for making observations at the same moment of time is for the construction of synoptic weather charts of large areas. For the transmission of observations by radio a separate publication, "Radiographic Weather Code for Vessel Weather Observers," is issued. Instructions for taking observations are printed in English, French, German, Italian, and Spanish. The requirements for observations are much the same as those of the Marine Branch of the British Meteorological Office, and the observations obtained are similarly used. Good explanations and illustrations are provided of the various instruments as well as of clouds and other weather observations, together with maps showing the use of synoptic observations over the Atlantic. A glossary is given of a number of meteorological terms of special interest to mariners and tables for the correction and reduction of observations.

The report of the Botanical Survey of India for 1924–1925, issued by the Director, Mr. C. C. Calder, is melancholy reading in one sense in that it states that owing to reduction in staff, effected "to secure the object of retrenchment," the Survey, "so far as field exploration is concerned," became "a Department in name only." On the other hand, much good systematic botanical work is chronicled by students of Indian botany both in India and abroad. An interesting report is also given of a further year's experimental work with cinchona in Burma. The Director concludes his account of the Burma plantations with the forecast that, if labour conditions are favourable, he sees no reason "why a large quinine producing belt extending from the Tenasserim River eastwards to the borders of Siam should not result and production on a scale sufficient to affect controlled prices and bring the drug within the reach of India's malarial millions."

The address given by M. Daniel Berthelot at the formal meeting of the Society of Civil Engineers of France, with the President of the Republic in the chair, held in celebration of the centenary of the publication of Carnot's tract "sur la puissance motrice du feu," is given in full in the issue of the *Revue Scientifique* for February 13. Born in 1798, Nicolas-Leonard-Sadi Carnot was only twenty-eight years of age when his brochure of 118 pages was published by Bachelier of 55 quai des Augustins, and eight years later he was carried off by an epidemic of cholera. In conformity with the sanitary regulations his effects were burnt, a small exercise book with scientific notes, now in the archives of the Paris Academy of Sciences, alone being saved. The tract excited little attention, and when Lord Kelvin in 1845 found a reference to it in a memoir of Clapeyron, he only succeeded in finding a copy after three years' search. Clausius in 1870 stated that he had not up to then succeeded in finding a copy, and at the present time it is almost unprocurable

The after-Easter Lectures at the Royal Institution will begin on Tuesday, April 13, at 5.15 P.M., when Prof. J. Barcroft will deliver the first of four lectures on organs of multiple function, (I.) "The Salivary Glands." These will be followed by three lectures by Dr. G. W. C. Kaye on the acoustics of public buildings (Tyndall Lectures); and two by Sir Percy Sykes on (i.) Shah Abbas of Persia, the contemporary of Queen Elizabeth, (ii.) Chinese Turkestan and the Pamirs. Thursday afternoon lectures include three by Sir William Bragg on the imperfect crystallisation of common things; two by Mr. U. R. Evans on corrosion, tarnishing and tinting of metals; and two by Dr. J. Newton Friend on (i.) iron in antiquity, (ii.) science in antiquity. Saturday afternoon lectures include two by Dr. W. T. Calman on the shipworm, beginning on April 17; two by Dr. G. C Simpson on atmospheric electricity; and one by Prof. Alexandre Moret on "Une Revolution sociale en Egypte vers 2000 Av. J.-C." (in French). The Friday evening discourses will be resumed on April 16, when Dr. A. W. Hill will deliver a discourse on the quest for economic plants. Succeeding discourses will probably be given by Prof. R. Whiddington, Dr. W. H. Eccles, Sir Frederic Kenyon, Mr. Seton Gordon, Sir Almroth Wright, Prof. J. Garstang, Prof. J. C M'Lennan of Toronto, and others.

Summer time will come into force in Great Britain and Northern Ireland, as well as in France and Belgium, at 2 o'clock, Greenwich Mean Time, on the morning of Sunday, April 18.

Sir Henry Miers, who is retiring this year from the Vice-Chancellorship of the University of Manchester, has been elected a trustee of the British Museum in succession to the late Dr. W. Bateson. Sir Henry was a member of the staff of the British Museum in the Department of Mineralogy from 1882 until 1895.

The summer meeting of the Institution of Electrical Engineers will be held at the North-Eastern Centre, Newcastle-on-Tyne, on June 8-11. The meeting will then be in the centre of an industrial district, and numerous visits to important works in the neighbourhood, as well as to places of more general interest, have been arranged.

Mr. A. Rodger, President of the Forest Research Institute and College at Dehra Dun, will succeed Sir Peter Clutterbuck as Inspector-General of Forests when the latter goes on leave preparatory to retirement, and will combine his new duties with the presidential duties already in his charge. According to the Delhi correspondent of the *Times*, this will mean the creation of a new appointment of professor of forestry at the Research Institute and College.

THE committee of the Manchester Museum, in its report for the year 1924–25, notes that the construction of the new building provided by the late Dr. Jesse Haworth, though delayed by labour troubles, is now progressing, and it adds that if this building is to be adequately maintained, an increase in the Museum's income is imperative. One step towards that end has been taken by the committee, on the lines of the American Museum of Natural History, in enrolling all annual contributors of five shillings or more as "Members of the Manchester Museum." The committee has also widened its basis by co-opting representatives of the chief scientific societies in Manchester We cannot but feel that the Corporation of this wealthy city might increase its grant to this excellent Museum, which took the lead in the education of school-children.

THE report of the meeting in London in April 1924 of the International Commission for the Exploration of the Upper Air has recently been issued by the Meteorological Office of the Air Ministry. The report is in English but the French text of the nineteen resolutions is also given in an appendix. The most important of these resolutions are: (1) Nos. (iii.) and (iv), which register the decision of the Commission to publish in collected form the full results of the International Investigation of the Upper Air in 1923 and 1924, thus renewing an international effort which had been in abeyance since the War; (2) No. (xv.), which expresses clearly the two main purposes of international exploration of the upper air, namely, the study of the general circulation and the more detailed study of the structure of the atmosphere in different regions for different types of weather; and initiates a system of deputy presidents charged with the supervision of the investigation in different regions of the world; and (3) a resolution on p. 32 of the report affirming that barometric pressure should be expressed in millibars, and that geopotential expressed in dynamic metres should be used in place of geometric heights. Among the appendices one notes a number of memoranda presented by the Russian delegate. Until records of *ballons-sondes* for Russia and Siberia are available for the same time as those made in the rest of Europe, the solution of many of the problems connected with the stratosphere cannot be achieved. The Commission indeed affirmed this by passing a special resolution (No. viii.) "that intensive observations of *ballons-sondes* in Russia and Siberia from 3-5 stations are of great importance in the investigation of the upper atmosphere."

THE American Geophysical Union now meets annually, and the transactions of the sixth annual meeting (1925) have been issued as a *Bulletin of the National Research Council*, vol. 10, part 3, No. 53, July 1925. The major part of the bulletin is, however, devoted to abstracts of reports and papers, covering a very wide field. W. J. Humphreys reports that a rocket is being developed with the aid of which it is hoped to obtain determinations of the temperature of the upper air at various heights, and also samples of gas from these heights, for chemical analysis; direct information on both these disputed questions is much to be hoped for. The bulletin also includes a series of reports, by the American delegates, of the meetings at Madrid (1924) of the International Geodetic and Geophysical Union and its various sections. The official report of the Madrid meeting, in October 1924, of the Section of Terrestrial Magnetism and Electricity of the International Geodetic and Geophysical Union, has been issued as Bulletin No. 5 of the Section's publications. It supersedes an earlier report issued in December 1924. The contents are too varied to be detailed here, but, besides collecting opinions on many important points of organisation and observation important for the progress of the science, the bulletin affords a valuable medium for publishing reports at regular intervals of work proposed or accomplished in the different countries. The resolutions passed at the meeting, urging the necessity of establishing more magnetic observatories in high latitudes, or improving the equipment of existing observatories, have already borne fruit in one or two important cases.

WITH reference to the article on the Report of the Coal Commission which appeared in NATURE of March 20, p. 405, and to the statement therein that concealed coal could only be discovered as the result of the labours of the Geological Survey, Messrs. S. and J. Bailey, Princes Chambers, 6 Corporation Street, Birmingham, write to point out that the knowledge of the existence of much of this coal has been derived from boreholes put down by individuals at their own expense, which has often been very heavy, and in many cases has brought them in no return. The knowledge of geological structure thus obtained has often been of value to the Geological Survey. These statements are perfectly correct, but it is obvious that had there never been a Geological Survey of Great Britain, individuals would have had little or no incentive for boring and would not have known where to bore. It is precisely because the labours of geologists have in the first instance made clear the structure of the hidden portions of the earth's crust in Great Britain that boring for a concealed coalfield was rendered conceivable, let alone feasible.

THE Chemical Society of Japan has commenced the issue of a monthly Bulletin, of which we have received No. 1, vol. 1, January 1926 This development has been made possible by the presentation to the Society of a gift of money made to Prof. Ikeda to celebrate his sixtieth birthday. The publication contains short chemical papers and abstracts.

FOUR more sets of charming coloured illustrations on postcards, each set containing six cards with descriptive folder, have been issued by the Royal

Botanic Gardens, Kew (1*s.* per set). The set with rhododendrons and azaleas are very seasonable, as also two delightful series of illustrations of hardy trees and shrubs; the coloured reproduction of Japanese cherries flowering at Kew is particularly successful, but all these are extremely effective. The fourth set deals with stove and greenhouse plants.

Applications are invited for the following appointments, on or before the dates mentioned:—A biochemist for the study of the nitrogen compounds in barley and their relation to malting—The Secretary, Institute of Brewing, Brewers' Hall, Addle Street, E.C.2 (April 14). A director of experiments at the Experimental Station of the Chemical Warfare Research Department, Porton—The Chief Superintendent, Chemical Warfare Research Department, 14 Grosvenor Gardens, S.W.1 (May 1). An investigator in the Metallurgical Department of the Royal Aircraft Establishment for work on the electro-deposition of metals—The Superintendent, R.A.E., South Farnborough, Hants (quoting A. 92). An analyst under the Air Ministry for duty in Irak—The Secretary, Air Ministry (W.B. 5), Kingsway, W.C.2.

Our Astronomical Column.

Two Fireballs.—Mr. W. F. Denning writes: "On Saturday, March 20, at 6.45 P.M., when twilight was still strong and but few stars visible, a fine meteor passed from E. to W. over the south of England. It was observed by many persons, for the weather was generally clear and the flight of the object extended over about 290 miles. Reports of its appearance have come from Bampton near Oxford, Neath (Glam.), Bristol, Dartmoor, Stratton, Fowey (Cornwall), and Watford (Herts). The descriptions are not in good agreement, but they indicate a radiant point near the E.N.E. horizon. The luminous path of the object apparently extended from Kent to a region of the sea about 35 miles N. of Land's End. The height is not exactly determinable, but appears to have been lower than usual. The meteor traversed its lengthy course at a velocity of about 29 miles per second

"On Sunday, March 21, at 8.13 P.M., a very large meteor was noticed from Bristol and other places in the west of England. It was a ball of fire which moved slowly amongst the stars of Taurus and Orion. At the end point it crumbled into pieces and died away amid thin white clouds in the S.W. sky. The radiant point was at 12° + 40° in Andromeda, and its height 65 to 29 miles; path, 90 miles; velocity, 23 miles per second. This meteor appears to have been noticed by very few persons who have troubled to describe its appearance."

Comets.—There are at last some definite post-perihelion observations of Ensor's comet; they were obtained at Bergedorf observatory by A. Schwassmann and J. Stobbe They gave exposures of 2½ hours with the Lippmann astrograph, and obtained images showing a tail half a degree long in position angle 250°, which is nearly at right angles to the line from sun to comet. The tail was forked at 20′ from what was taken to be the head, but as there was no trace of a nucleus it is difficult to know what point to select for measurement. The positions they give are:

	U.T.	R.A.	N Decl.	Obs minus Tab.	Mag.
March 16d	$1^h\ 12^m$	$21^h\ 47{\cdot}9^m$	49° 6′	$+0{\cdot}2^m$	−3′	12
20	19 5	22 23 0	59 20	+0 4	−3	13

The tail was fan-shaped, its angular opening being 10°. The rapid decline in light after perihelion was quite unexpected.

Comets Borrelly, Brooks, Tuttle, Orkisz, and Van Biesbroeck have also been photographed recently at Bergedorf observatory, which makes a speciality of observing faint comets. Comets Borrelly and Brooks have now been under observation for six months, so there is ample material for improving their orbits. Van Biesbroeck's comet continues to be an easy object though nearly six months from perihelion.

The Eclipse of Odysseus.—Herr C. Schoch has written further about this eclipse, noting the corroborative facts that Homer's narrative states that the day in question was the day of new moon, and that the time of the darkness was somewhere in the neighbourhood of noon, agreeing with calculation, which gives $11^h\ 41^m$ A.M. local time. The prophet's words, "The sun is lost from the heaven, and evil darkness has come," certainly accord well with totality. Moreover, his tables, which were based on many ancient eclipses and occultations, place the northern part of Ithaca inside the track of totality. There was no other totality at Ithaca within 200 years.

Herr Schoch agrees with Dr. Fotheringham in the value used for the sun's acceleration, 2·64″ per century, but his other data are not quite the same; his centennial motion of the moon is 1″ greater than Fotheringham's. He claims that his values represent the occultations of the Almagest considerably better than Fotheringham's. He supposes that the Odyssey was written three or four centuries after the events described, but considers that the eclipse results make it probable that some trustworthy traditions of those events had come down.

A Remote Stellar System.—A study of that most interesting object N.G.C. 6822 is given by Hubble in the *Astrophysical Journal*, vol 62, p. 409. This system is a very faint cluster, closely resembling in many ways the Magellanic Clouds, both in its constituent objects as well as in general appearance, though of course it is apparently much fainter and smaller than those Clouds. Throughout the two seasons of 1923 and 1924 it was carefully observed by the author, who has obtained some fifty negatives, as well as several spectrograms, with the great reflectors of the Mount Wilson Observatory. He has found fifteen variable stars in the cluster, eleven of which are Cepheids, and five diffuse nebulæ similar to those found in other systems. The period-luminosity law for the Cepheid variables is well shown, and a comparison with Shapley's curve indicates a distance for the cluster of 214,000 parsecs (about 700,000 light-years). This enormous distance shows that the cluster must lie far beyond the limits of the galactic system; but it is corroborated to some extent by a comparison of the cluster with the Magellanic Clouds, as regards angular dimensions, luminosities of the nebulæ and of the brightest stars. Shapley had previously made such comparison, and judged the distance of the cluster to be of the order of 1,000,000 light-years. The brightest stars present appear to be of absolute magnitude about −5·9, which is in satisfactory accordance with other isolated systems such as our own local cluster and the Magellanic Clouds.

Research Items.

Archæology in Kenya Colony.—In the January number of the *Journal of the East Africa and Uganda Natural Historical Society*, Mr. G. W. B. Huntingford points out that while the antiquities of Kenya Colony provide a considerable amount of material for investigation, although it is confined to certain areas, very little attention has been paid to local archæology. The greater number of the antiquities occur in the districts of Uasin-Gishu and Nandi, with, it is believed, some in the Tanganyika territory. There are several classes of these antiquities, of which the more important are: (*a*) enclosures of stone or earth with double or single walls confined to Uasin-Gishu and not occurring in Nandi; (*b*) hut-circles occurring throughout the Eldoret area and with still more frequency in Nandi; and (*c*) pit-villages, groups of hut-circles usually earthen, some of which are even double or treble. In addition there are artificial mounds—at least two have been observed—a menhir on the summit of a hill on the western Nandi escarpment, and remains of 'roads' and irrigation canals and rows or low ridges which suggest graves. A number of 'finds' include pottery differing in character from the Nandi pottery, and a number of stone implements of various types. As regards the builders of the ruins, in the absence of excavation, no very convincing suggestion can be made, although it is clear that they were the predecessors of the present inhabitants of the area and possibly came from the north. The Sirikwa branch of the Uasin-Gishu Masai have been suggested, though certain considerations militate against this and point to these people having found the circles built when they came, while the Keyu (Elgeyo) tradition says the builders were a 'red' race, which may indicate a people of Libyan origin. There appears to be no connexion with the Zimbabwe culture, though the ruins may represent the early work of the Zimbabwe race.

Archæological Investigations at Chichen Itza, Yucatan.—Dr Sylvanus G. Morley's report on Middle American archæological research in Year Book 24 of the Carnegie Institution, Washington, covers the operations of the year 1924, when the activities of the Institution were concentrated at Chichen Itza. The most extensive piece of work undertaken was the complete clearance of the Temple of the Warriors and its partial repair. This work was under the care of Mr. R. H. Morris, who furnishes a detailed report. This building, it now appears, was one of the most important in the whole city. It is second only to the Castello in size and exceeds it in wealth of sculptured decoration. The pyramid supporting the temple covers two-thirds of an acre and rises in four terraces or steps to a height of 37 feet above the paved level of the Group of the Thousand Columns. The three lower terraces have their cornices elaborately sculptured with men, eagles, jaguars, and another as yet unidentified animal with a woolly covering. These were originally painted in brilliant colours. The interior and exterior walls of the temple were also once brilliantly painted, but the collapse of the roof has wrought irreparable damage to the frescoes. Originally there were twenty-two painted and sculptured columns, of which two—feathered serpents—stood in the doorway. Against the back wall was a sculptured and painted altar supported by nineteen painted Atlantean figures. During the repair of the Astronomical Tower, which was undertaken to preserve from shifting the passage ways formerly serving as astronomical lines of sight, a hieroglyphic band was discovered. This gives a date now deciphered as 3 Imix 9 Yax, Tun 1, which is interpreted as A.D. 1280. Six lintels discovered, four at Chichen Itza and two from Yula, apparently coincide in their day of dedication—a Tun 13 ending on a day 1 Ahau—for which a probable date is A.D. 1155.

Climate and Plant Distribution.—In a lecture delivered before the Royal Geographical Society on February 15, Dr. E. J. Salisbury discussed very fully the relation between the geographical distribution of plants and climatic factors. Although the effect of the various climatic factors upon plant growth is primarily one for investigation by the physiologist, yet the application of the results of these investigations must continue to remain the province of the ecologist or plant geographer, whose particular outlook must be much more influenced by the conception of competition as a factor of vital importance. Climate may delimit three zones in the distribution of a given plant, namely: a zone in which both abundant vegetative growth and reproduction are possible; a second zone, in which normal vegetative growth ensues but reproduction is possible only in exceptional seasons; a last zone, in which the plant may be cultivated but will not reproduce. To be of real use, plant distribution maps should, therefore, also indicate the relative abundance in different areas of the species under consideration. Dr. Salisbury also pleads for detailed maps showing the actual rainfall not corrected to mean sea-level, and for maps showing the seasonal distribution of rainfall.

Insect Pests in American Agriculture.—The report for 1925 of the U.S. Bureau of Entomology, by Dr. L. O. Howard, the chief of that organisation, has recently come to hand. It forms a record of an enormous range of activities distributed over the whole of the United States. While the progress achieved in the control of the cotton boll weevil and gipsy moth, for example, is encouraging, there are certain other major pests that seem to defy all efforts to restrain them within bounds. The European corn borer is reported to have added nearly 9000 square miles to its area of infested territory during the year. It is hoped that the enactment of compulsory legislation providing for the cleaning up of infested fields will facilitate the repression of this pest. The discovery of the alfalfa weevil in eastern Wyoming marks the entry of that insect into the extensive alfalfa region of the Mississippi basin. The Mexican bean beetle is also continuing to spread rapidly in a northern direction, it having reached the shores of Lake Erie and extended its range in other States. The report is a striking testimony to the severity of the warfare between man and insects, and how the resources of an army of investigators are being employed to attack big problems from all points of view.

Placentation in Lizards.—Prof. Harrison and Miss Weekes (*Proc. Linn. Soc., N.S.W.*, vol. 1, pt. 4, 1925) give a preliminary account of their discovery of a true placenta in an Australian lizard, *Lygosoma entrecasteauxi*. Both omphaloplacenta and allantoplacenta are present. The former is in a state of regression but shows evidence of having been more actively functional at an earlier stage. The allantoplacenta comprises a uterine part, of vascular villous ridges with modified epithelium, and a fœtal part, with greatly modified chorionic ectoderm and a complex allantochorion. True placentation has already been recorded in other lizards, and the authors suggest that the occurrence of this condition in two not very closely allied genera such as Lygosoma in Australia and Chalcides in Europe indicates that the allantoplacenta is a functional adaptation which may have arisen independently many times in evolution, and upon the mere occurrence of which phylogenetic statements cannot justifiably be based. A consideration of reptilian placentation as a whole leads the authors to suggest three stages of placentation, chorioplacenta, omphaloplacenta, and allantoplacenta, arising in that serial order both in ontogeny and phylogeny.

A Fossil Branchiopod.—Mr D. J. Scourfield publishes in the *Philosophical Transactions of the Royal Society*, B, 415, 1926, an account of an extremely interesting branchiopod crustacean from the Rhynie chert bed of the Old Red Sandstone. The species, which he names *Lepidocaris rhyniensis*, is minute, not exceeding 3 mm. in length, and probably lived in water which was hot and strongly charged with silica, by which the specimens have been beautifully preserved. It has no carapace, and in many features resembles the Anostraca, but differs from them in certain important respects. On this account a new order, the Hipostraca, is created. There are apparently no paired eyes. The antennules are three jointed and the antennæ biramous swimming organs. The mouth parts resemble those of the Anostraca, save that to the maxillules (probably) there is attached, in the male, a large clasping organ. The first three pairs of trunk limbs are phyllopodia, resembling those of the Anostraca, but having the first endite replaced by two, of which the proximal resembles the gnathobase of the Conchostraca. The remainder of the trunk limbs are of a peculiar biramous type. Curious movable scales lie above the origin of the trunk limbs. The last three segments are limbless and are succeeded by a long telson which retains the primary furca of the larva together with the secondary furca.

Fossil Footprints from the Grand Canyon.—An account has recently been published by Dr. Gilmore (*Smithsonian Miscellaneous Reports*, vol. 77, No. 9) of fossil footprints from the Grand Canyon These occur in the Coconino sandstone of Permian age, and the 'fauna' is represented by eight genera and ten species of vertebrates and two of invertebrates. No other trace of the animals that made these footprints has as yet been discovered, and for the majority of them no attempt is made to connect them with any actual animals known from elsewhere. In two cases, however, the impressions suggest forms strongly suggestive of, in one case the light lizard-like Aræoscelis, and in the other the heavier Stegocephalian Cacops. In the absence of other criteria, these tracks have some value in the geological correlation of these deposits with similar track-bearing deposits elsewhere. Dr. Gilmore is returning to the Grand Canyon to continue his investigations.

Survey Work in the United States.—In his annual report for 1924–25, the Director of the United States Coast and Geodetic Survey records a great increase in the amount of hydrographical work accomplished, owing largely to the acquisition of several large modern and well-equipped vessels. In Alaskan waters, surveys have made great progress, both in the west and on the south-east coast. Other important surveys were made on the Oregon and Californian coasts, and revision work has been done on the Georgia and Florida coasts. The survey of the Virgin Island waters is nearly completed, and good progress has been made in the Hawaiian and Philippine coastal waters. Of the geodetic work of the survey, probably the most important was that carried out along the boundary between Canada and the United States to the west of Lake Superior, but a great deal of other work was successfully undertaken. The report is fully illustrated with large-scale maps showing the progress of all surveys.

Polar Form of Ethylene Linkage.—Attempts to determine experimentally whether compounds containing the ethylene linkage exist in a polar form have been made by a quantitative study of the reaction with the Grignard reagent. The experiments by H. Gilman and J. M. Peterson are fully described in the *Journal of the American Chemical Society* for February. Under the conditions of the experiments, no active or polar forms appear to exist, or the active forms are present only in extremely small concentrations or are not sufficiently active to react with the Grignard reagent.

Melting Points of Calcium, Barium, and Strontium Oxides.—Some trustworthy values for the melting points of barium, calcium, and strontium oxides are given in the *Journal of the American Chemical Society* for February by E. E. Schumacher. Samples from several different sources were heated electrically in a tungsten boat supported on molybdenum rods in pure hydrogen at 0·2 atmosphere pressure. A carefully standardised optical pyrometer was employed to read the temperatures. The results are: calcium oxide 2576° C., barium oxide 1923° C., and strontium oxide 2430° C.

Eka-Iodine and Eka-Cæsium.—The possibility of the 'missing' elements of atomic numbers 85 and 87, eka-iodine and eka-cæsium respectively, occurring in a subsidiary disintegration series of one of the radioactive elements, is discussed in an interesting article by Prof. O Hahn in *Die Naturwissenschaften* for February 26 The nature of the surrounding elements makes this very probable, although it is pointed out that since eka-iodine and eka-cæsium have odd atomic numbers, one would expect to find only very small quantities as compared with the proximate radioactive elements of even atomic numbers. Attempts to isolate an active cæsium from a highly active mesothorium preparation containing radium are described, but the results obtained were completely negative.

Electric Salt Bath Furnaces.—The Allgemeine Elektricitätsgesellschaft of Berlin publishes every month a journal in English called *A.E.G. Progress*, of interest to engineers. The January number discusses such subjects as the life and operating trustworthiness of turbo-generators, self-regulating dynamos, wind-electric installations, benzol locomotives, etc. We were particularly interested by an article on electric salt bath furnaces. In the A.E.G. hardening furnace, a bath of molten salt is connected across the secondary of a transformer. The bath itself acts as the resistance and secures a uniform distribution of heat. The furnace is used for annealing, hardening, tempering and surface hardening (carbonising) For hardening tools of high-speed steel it generates temperatures up to 1300° C. The regulation of temperature is done by simply altering the voltage applied to the transformer. A protective hood placed over the furnace protects the operator from the heat radiated. Three-phase power is used to operate it Special mixtures of salts are generally used. For hardening high-speed steel the best salt to use is barium chloride, but for carbon steel it is better to use a mixture of barium and potassium chloride. A claim is made that an important saving is effected by the improved quality of the work and the certainty of the action of the furnace In a South African mine, the plant employed is capable of dealing with 6000 drills in eight hours at a cost of about two shillings per 100 drills. Asbestos gloves and coloured glasses are used by the operators.

Santal Medicine.[1]

THE Santals are one of numerous aboriginal tribes inhabiting those hilly tracts of western Bengal that extend southwards from the Ganges into Chutia Nagpur They are—or were—distinguished for their bravery, independence, and love of sport It was of the Santals that an English magistrate, coming among them with an official experience limited to the low-lying eastern districts of Bengal, complained that they confused him by their obstinate adhesion to the simple truth, or, as his Bengali clerk is said to have expressed it, by their ignorance of the value of a lie. More than other untutored races do Santals live in dread and constant appeasement of malignant spirits, or *bongas*. So much do these *bongas* exclude the supreme but impassive good spirit from men's minds that the earliest European missionaries, seeking among the people for some native concept of the supernatural upon which to ingraft the theology and message of Christianity, are said to have based their first unhappy attempts upon a misconception of the nature of a *bonga*.

Santal medicine, like that of the vast mass of humankind, consists of superstition tinctured with *materia medica*; but from the memoir under review, one gathers that among the Santals the superstitious element, though much preponderant, is strangely logical. The supreme excellent spirit, Cando, desires that all Santals shall live to a good old age. He may, though slow to anger, visit the whole congregation with an overwhelming punishment such as famine, but the idea of slitting the individual thread by disease is not a part of his plan Sickness must needs occur during the allotted span; but Cando has provided a sufficiency of herbs of powerful grace, which restore health. This being the ordained plan, it is useless to try to get it changed by individual supplications. For the given disease the given remedy is already provided in Nature: it may be a household remedy known to all men, or it may be known only to persons who have acquired an extensive knowledge of diseases and their appropriate treatments. The author states that there are among the Santals persons professing such knowledge, who treat the sick solely and simply under Cando's good providence, without invoking supernatural aid. Such persons he calls 'medicine men'; but if only they had received—as they have not—a professional training, they would come nearer our idea of an orthodox physician.

The true signification of 'medicine man' belongs rather to the *ojha*, a more pretentious person, who, while professing a knowledge of diseases and of natural remedies, professes also to have acquired, by special training and formal initiation, a knowledge of the supernatural which explains why the sick man does not recover, or recovers only to relapse. Serious menacing disease is due mainly to *bongas* and ancillary witches, and can be treated only by the *ojha* with perhaps the co-operation of the *ján* or witch-finder. The *bongas* can only do damage; they have neither the will nor the power to heal. They act not directly, but through human errors and through ubiquitous *tejos*, which, like microbes, exist in great numbers in the body—*e g.* scabies, ringworm, leprosy, rabies, etc., are due to the activity of *tejos* The witches also act indirectly, by secretly obstructing the efforts of the *ojha* to discover and appease the appropriate *bonga*.

The *ojha* is on familiar terms with the *bongas*. If by proper divinations, incantations (*muntars*), and sacrificial vows (*sakets*), he can get in touch with the responsible *bonga*, he may be able to appease it and can then apply his pharmacology. His attempts at communication with the *bonga* may, however, be obstructed or diverted by a witch, and then the assistance of a *ján* may be necessary. Witches, of course, are not treated by propitiatory methods—*tout au contraire*

It is notorious that the beliefs of most of the aboriginal races of India have been modified—sometimes absorbed—by the circumambient insinuating Hinduism, and the Santal theory of disease is a good example of the process. As the author points out, the *ojha* with his *muntars* (Hind. *mantra*) and *sakets* (Hind *sankt*), and the *ján* are of Hindu origin—their names bewray them. Among the *bongas*, too, there is a special contingent with Hindi names The conclusion therefore seems obvious—although the author makes no explicit statements—that the remaining and more rational parts of the theory are indigenous, and that the Santals, with their characteristic commonsense, have made a remarkably sagacious setting of the heavy exotic superstitions.

This interesting memoir in this first instalment deals in minute detail with all the paraphernalia of superstition A second instalment, treating of *materia medica* and medical treatment, is stated to be in the press.

Egyptian Fisheries.[1]

NEARLY all the fisheries of Egypt lie within the territorial boundaries and are State owned. In 1924 they brought in to the Government the substantial income of some 83,000*l*.

There are three main sources from which the fish supply is drawn: (1) The Nile and inland waters, including basins and irrigation canals; (2) the Mediterranean and, to a small extent, the Red Sea; and (3) the Delta lakes. Of these three fisheries, that of the Delta lakes is by far the most important, yielding a yearly catch equal to two-thirds of the total fisheries. In the Mediterranean, Egypt possesses, in addition, very fine sponge beds within her territorial waters along the north coast of Africa, west of Alexandria.

Little information of scientific interest about the fisheries was available to the public up to 1919, except for the interesting chapter on nets and gear in use on the lakes and inland waters by Loat in Boulenger's "Fishes of the Nile." In 1919, however, the Coastguards and Fisheries Service, under the disciplinary control of which the fisheries now lie, secured the services of a scientific and technical assistant, Mr. G. W. Paget. From that date we received annually reports of great interest In April 1924 the Government closed down the Fisheries Research Section.

Between these dates the mere economic value of such an office became apparent to any one reading the reports. Of outstanding interest was a large stocking experiment that has proved an unbounded success. Of the four Delta lakes—Menzaleh, Brullos, Edku, and Maryût—the first three are either permanently, or temporarily during the year, connected to the sea by narrow straits. This allows of the population of these waters by immense numbers of grey mullet, chiefly *Mugil cephalus* and *M. capito*,

---

[1] Report on the Fisheries of Egypt for the Year 1924. By Kaimakam G. Jenkins Bey. Coastguards and Fisheries Service. Ministry of Finance, Egypt. (Government Press, Cairo.) P.T. 5.

These fish, which form a very large percentage of the lake catches, migrate to the sea from the lakes to spawn. Where exactly the eggs are laid is not known, none having yet been certainly identified. As a result of the spawning, countless fry, under an inch in length, make their way back through the straits to the lakes, there to renew the stock, being attracted thither by the outflow of comparatively fresh water into the sea.

Lake Maryût, however, is at no time directly connected with the sea, the water-level being kept down by the action of immense pumps. The mullet fry are attracted by the outflow of fresh water flowing down the canal from the pumps into the sea, they swim up this canal, but their way into the lake is barred by the pumping-station. Consequently, the mullet fishery in this lake was negligible up to 1920 In that year Paget inaugurated stocking operations, whereby these fry were captured at the pumps and taken in a specially designed transport boat far out into the lake, where they were released. The following figures speak for the success of the operation. The number of fry introduced varies from year to year, but is in the neighbourhood of 30 millions. The actual lake-side weight of grey mullet caught rose from practically nil in 1920 to 223 tons with a lake-side value of E17,500*l*. in 1923, and to 406 tons in 1924, and is still rising. The actual cost of transport of the fry remains at about 350*l*. per annum. As a direct result of this experiment, Paget was further enabled to study accurately the rate of growth, under natural conditions, of the fish through three years, and to correlate growth with scale markings, with the advantage of knowing the size at which they were put into the lake The closing of the Research Office prevented this interesting problem from being carried through the later years of the fish's life

It is at any rate gratifying to note in the 1924 report, compiled by Kaimakam Jenkins Bey of the administrative staff, that attempts are being made to continue stocking the lake and also that other schemes of a somewhat similar nature, designed to improve the fisheries of the lakes and inland waters generally, that Paget had planned, are now being put in action. Amongst these is a method of driving, by means of fine-meshed nets, thousands of young fish into the main waters of the Nile from flooded areas that dry up in the heat of the summer, thus causing much waste of fish life.

A further source of valuable information to the Government was a survey of the sponge beds along the north coast of Africa, made in 1919 These beds, up to 1915, had been exploited by nomadic Greeks, who took their catches home with them From that date until 1920 the fishery lapsed on account of the War. The 1919 survey provided a basis for determining to what extent the beds will bear fishing without producing effects that may be harmful to the crops of future years. The fishery is now run on an economically sound basis and is put up to auction each season by the Government, the fishing fleet being licensed and their catches inspected at regular intervals.

It is surely false economy for a Government to dispense with an office, in no wise costly, that renders such signal service. It is, however, perhaps a promise of better things in the future to read the following passage in a covering letter to the 1924 report:

"For motives of economy the Fisheries Research Section was closed down in April 1924 and the service of the Staff dispensed with, consequently no improvement in the conditions of the industry can be expected in the future except through natural causes until such time as the situation allows for the re-establishment of the Research Section, to study local conditions, to make scientific observations and to conduct experiments with a view to increasing the fish supply and to recommend methods for preventing the destruction of immature fish."

F. S. R.

Peat in the British Isles.

A PAPER not without importance in its application to one aspect of afforestation work in Great Britain and Ireland appears in the *Empire Forestry Journal* (vol. 4, No. 2, 1925). This paper bears the title "Types of Peat and their Connexion with Afforestation," and is by Mr. A C. Forbes, Director of Forestry, Irish Free State. The problem of afforesting peat lands has been the subject of experiment for a considerable period of years in various parts of Europe, and in the British Isles two notable examples exist. The opinions of experts in this branch, based on experimental work, can scarcely be said to have been unanimous.

Mr. Forbes' paper is of value on one count, since he directs attention to the fact that the term 'peat' as used in the past has resulted in considerable confusion, and as a consequence the values of experiments undertaken have become either misleading or altogether useless for other regions or countries. The author roughly classifies what he terms 'peats proper' into five classes: (1) Turf peat, (2) heath peat, (3) mountain peat, (4) sphagnum peat, and (5) marsh peat. He shows that, so far as the bulk of the peat areas which may be of importance for afforestation purposes in the British Isles are concerned, the mountain peat is the most important. Forbes says that the confusion arising in the past, especially in connexion with German literature, has been occasioned by endeavouring to apply experiments which have proved satisfactory in the case of marsh peat to the other types of peat of his classification. "Mountain peat," he says, "is developed under humid conditions and usually at high elevations. Owing to the climatic conditions being favourable to sphagnum development, mountain peat accumulates faster and attains a greater thickness than heath peat, and may often terminate in pure sphagnum, the lower layers of which solidify, and cut off the connexion between the soil water and the surface" Mountain peat extends down to sea-level on the west coast of Ireland and Scotland and in Somerset and Devon not much below 1500 ft. The author hazards the statement that there may be no less than 10,000,000 acres covered with peat in Great Britain and Ireland. The two examples of attempts to plant mountain peat on any scale were at Knockboy, County Galway, which was a failure, and the classic work carried out by Sir John Stirling Maxwell at Corrour, a high-lying valley on the Moor of Rannoch, which is considered to be a partial success.

The author puts forward his term of 'mountain peat' with an apology, and states that 'tundra' might be a better term, though a word seldom used in the English language. The word 'tundra,' however, is essentially applied to the great marshy and peaty wastes in North Russia and elsewhere. These by the author's own showing fall under his (5) marsh peats. The term 'tundra' would therefore be misapplied to the mountain peat.

University and Educational Intelligence.

Aberdeen.—The Senatus Academicus has appointed Dr. J. L. McIntyre, lecturer on comparative psychology, a member of the Faculty of Arts.

At the Spring Graduation the honorary degree of LL.D. was conferred on Dr. R. W. Reid, emeritus professor of anatomy in the University. The following doctorates were conferred: D.Sc. on Mr. J. M. Henderson for a thesis on "The Influence of Ultra-Violet Light on the Mineral Metabolism of Growth and Lactation"; Ph.D on Mr. W. M. Dickie for a thesis entitled "The Scientific Method and Achievement of Aristotle and Bacon"; and on Mr. F. C. Kelly for a thesis entitled "The Role of Iodine in Nutrition."

The Vice-Chancellor announced bequests amounting to about 25,000*l*., bringing the total addition to the endowments of the University since the War to more than 200,000*l*.

Edinburgh.—Prof. P. S. Lelean has taken up duty as professor of public health.

Principal Ernest Shearer, of the Edinburgh and East of Scotland College of Agriculture, has been appointed professor of agriculture in the University in succession to Prof. J. A S Watson, now of Oxford. This appointment, which is the outcome of negotiations between the University and the College authorities, will lead to a more intimate relationship between the two Departments.

London.—Prof. L Dudley Stamp has been appointed as from August 1 to the Sir Ernest Cassel readership in economic geography tenable at the London School of Economics. During the latter part of the time Prof. Dudley Stamp was on war service, he carried out extensive research work on the ancient geography of north-west Europe, for which he was awarded the Gosselet Medal and Diploma by the Société des Sciences (University of Lille). From 1921 until 1922 he was geological adviser to oil companies in Burma, and since 1923 he has been professor of geography and geology in the University of Rangoon. His published work includes "An Introduction to Stratigraphy" (1923) and numerous papers in the geological periodicals.

Mr. R. B. Forrester has been appointed as from August 1 to the Sir Ernest Cassel readership in foreign trade tenable at the London School of Economics. Mr. Forrester was formerly a lecturer in commerce at the School. In 1925 he published a Report on "Large Scale Co-operative Marketing in the U.S.A." (Ministry of Agriculture Economic Reports, No. 4). He is recorder to Section F (Economics and Statistics) of the British Association.

It has been resolved to institute an Academic Diploma in Anthropology.

Applications are invited for two Ramsay Memorial Fellowships for chemical research—one for candidates educated in Glasgow—each of the annual value of 250*l*., plus a possible further sum of not more than 50*l*. a year for expenses. The tenure of the fellowships is normally two years, but an extension to a third year is permissible. The latest date for the receipt of applications, which should be sent to the Secretary of the Ramsay Memorial Fellowships Trust, University College, Gower Street, W.C.1, is June 5.

Applications are invited by the Royal College of Physicians of Edinburgh for the Dr. Jessie Macgregor prize in medical science, value 63*l*. and open to medical women who are graduates in medicine of the University of Edinburgh, or who have taken the triple qualification, and who, before becoming qualified, have studied medicine for at least one year in Edinburgh. The latest date for the receipt of applications, by the Convener of Trustees, the Royal College of Physicians, Edinburgh, is June 30.

The Rose Research Fellowship in lymphadenoma, at St. Bartholomew's Hospital, the annual value of which is 600*l*., plus expenses, will shortly be awarded. The research will be carried out at the Hospital under the direction of the professor of pathology, and the fellowship may be tenable, under annual re-election, for a period of four years Further information may be obtained personally from the professor of pathology, St. Bartholomew's Hospital, London, E.C.1, to whom applications should be sent by April 21.

Secondary education in the United States is developing along lines which point to its extension both upwards and downwards by undertaking, on one hand, the first two years' work of the hitherto normal four-years' college curriculum and, on the other hand, the seventh and eighth years' work of the elementary schools. California led the way in what is known as the 'junior college' movement, and has been followed by Illinois, Michigan, Minnesota, Missouri, Texas, and other States. Owing partly to these developments, but still more to the remarkable increase during the past five and twenty years in the number of their pupils (from 9·5 to 23 per thousand of population), the problems presented by the secondary schools in the United States to-day are many and complex. To stimulate, initiate, aid, and co-ordinate their investigation, a "National Committee on Research in Secondary Education" has recently been established in close relationship with the Bureau of Education. The chairman is J. B. Edmonson, professor of secondary education of the University of Michigan, and the secretary is E. E. Windes, a member of the staff of the United States Commissioner of Education.

The Government has decided to offer the Bloomsbury site, purchased five years ago for the University of London, to the vendor, the Duke of Bedford, on the ground that "no effective scheme for the utilization of the site" has matured. The Vice-Chancellor (Prof. E. A. Gardner) has issued a memorandum, the object of which is to show "how little the University can be blamed for being either dilatory or vacillating." The Vice-Chancellor states that "the movement of King's College from its existing site in the Strand to Bloomsbury was an absolute condition of the offer." On this question, it may be said, opinion is not unanimous, and it is significant that the establishment of King's College on the site was not made a condition in the agreement between the Duke of Bedford and the Government. It is true that Mr. Fisher's offer of April 7, 1920, was accepted by the Senate on October 20, 1920, but this acceptance was subject to onerous conditions. The existence of cross-currents is also indicated by the fact that so late as October 1925 the Senate informed the Government that the question of increased accommodation at the Imperial Institute was a matter of great urgency It may be admitted, however, that if the removal of King's College was an absolute condition of the offer of the Bloomsbury site, the delay which has occurred can be readily understood. The Vice-Chancellor states at the end of his memorandum that "it is clear that the site can be effectively used for 'University and College buildings in connection with the University of London' within the much wider terms of the agreement between the Government and the Duke of Bedford. . . . If this area is now lost to education, it or more expensive land in the same neighbourhood or near by will have to be acquired again later, bit by bit, by the University or its Colleges." We may surmise that if the University in 1920 had spoken in these clear ringing tones the course of the negotiations with the Government might have taken a different turn.

Contemporary Birthdays.

April 1, 1874. The Rt. Rev. E. W. Barnes, F.R.S., Bishop of Birmingham.
April 2, 1853. Prof. P. Phillips Bedson.
April 3, 1846. Dr. B. Daydon Jackson
April 4, 1852. Prof. Arthur P. Coleman, F.R.S.
April 5, 1849. Prof. George Forbes, F.R.S.
April 5, 1865. Sir John Bretland Farmer, F.R.S.
April 6, 1864. Sir William Bate Hardy, F.R.S.
April 8, 1859. Mr George William Lamplugh, F.R.S.
April 8, 1861. Prof. J. R. Ainsworth-Davis

Dr. Barnes, Bishop of Birmingham, was educated at King Edward's Grammar School, Birmingham, and Trinity College, Cambridge Wrangler and second Smith's prizeman, he was ordained in 1902, becoming in the same year an assistant tutor at Trinity in mathematics; afterwards (1908–15) he was tutor. From 1915 until 1919 Dr. Barnes was Master of the Temple.

Dr. Bedson, emeritus professor of chemistry in Durham College of Science, was educated at Fairfield School, Manchester, at the Grammar School there, and at Owens College. He also studied at the University of Bonn.

Dr. Daydon Jackson is a Londoner. General Secretary of the Linnean Society since 1902, he is perhaps best known to botanists through his close association with the preparation and issue of the *Index Kewensis*. He is responsible for many useful works for botanical students, notably "A Guide to the Literature of Botany" (1881); and "A Glossary of Botanic Terms" (1916).

Dr. Coleman, emeritus professor of geology in the University of Toronto, was educated at the Victoria University, Cobourg, Canada, and at the University of Breslau. At the former he was (1881–90) professor of geology and natural history. He was geologist to the Bureau of Mines of Ontario, 1893–1909, accomplishing highly important work. Murchison medallist of the Geological Society of London, he has added largely to knowledge of the history of the stratified systems and of the igneous rocks of Canada. Dr. Coleman was president of Section C (Geology) of the British Association at the Sheffield meeting (1910).

Prof. George Forbes was educated at the Universities of St. Andrews and Cambridge. He is a Chevalier of the Legion of Honour of France. Sometime professor of natural philosophy in Anderson's College, Glasgow, he afterwards devoted himself to electrical projects. Prof. Forbes was electrical engineer for the first series of installations at Niagara Falls, 1891–95.

Sir John Farmer, professor of botany in the Imperial College of Science and Technology, graduated at Magdalen College, Oxford. He is a member of the Advisory Council of the Department of Scientific and Industrial Research. In 1919 he received a Royal medal from the Royal Society for his researches in the cytology and anatomy of plants.

Sir William Hardy was born at Erdington. He received his education at Framlingham College and Gonville and Caius College, Cambridge. After some years' service, he retired last year from office as one of the secretaries of the Royal Society.

Mr. Lamplugh was born at Driffield, East Yorkshire. He joined the Geological Survey of Great Britain in 1901, becoming Assistant Director, 1914–20. He is a past president of the Geological Society.

Societies and Academies.

London.

Royal Society, March 25.—**E. B. Verney**: The secretion of pituitrin in mammals, as shown by perfusion of the isolated kidney of the dog. When the head and neck of a dog are switched into perfusion-parallel with the isolated kidney, the blood picks up during its passage through the head and neck a substance or substances which inhibit the polyuria of the isolated kidney, augment the urinary chloride output percentually, or sometimes absolutely, and diminish the renal blood flow. This result is still obtained after previous exposure of the pituitary body. It does not occur as the result of perfusing the pelvis and lower limbs in parallel with the kidney. Previous removal of the pituitary body abolishes the reaction. An antidiuretic, chloride-augmenting, and vaso-constrictor principle or principles are contributed by the pituitary body to blood during its passage through the head of a dog.—**H. W. Florey** and **H. M. Carleton**: Rouget cells and their function. Capillaries in cat's mesentery have been studied by a method which enables blood-vessels to be selectively stained by intra-arterial injection of fixative and stain. Morphologically definable Rouget cells cannot be identified. *In vivo*, capillaries reacted to mechanical stimuli and particularly to the action of histamine and pituitrin. While capillaries are capable of actively expanding and contracting, their motor activities reside, not in Rouget cells, but in the endothelial elements.—**R. M. Sargent**: The relation between oxygen requirement and speed in running. A modification is described of the usual method of determining energy expenditure during running. The subject does not wear a mouthpiece, or carry a Douglas bag, and the exercise can take place under natural conditions. The results show actual energy expenditure and that involved in 'start' and in 'pull-up.' For the subject of these experiments to run 120 yards in 13 seconds necessitated an energy expenditure equivalent to an oxygen requirement of 29 litres per minute, or to 13·7 horse-power. There is extreme energy cost for rapid and vigorous exercise of short duration. An approximate means of allowing for energy utilised in 'start' and in 'pull-up' is adopted. Then the general relation between speed in running and oxygen requirement is: Oxygen requirement per 120 yards increases about as the 2·8th power of speed. Oxygen requirement per minute increases approximately as the 3·8th power of speed. The calculated optimum performances agree well with those actually recorded (or estimated) by the subject, over the range 300 yards to 2 miles.—**Seana King**: Oogenesis in *Oniscus Asellus*.—**J. L. Synge**: On the geometry of dynamics. The representation of configurations by points of multi-dimensional Riemannian space has been used hitherto to discuss certain aspects only of classical dynamical theory. In the present paper, tensor notation is used throughout, and to the advantages of this notation the novel results are due. Parallel discussions are given corresponding to two line-elements—the 'kinematical' line-element, $ds^2 = 2T dt^2 = a_{mn} dq^m dq^n$, and the 'action' line-element, $ds^2 = 2(h - V) T dt^2 = (h - V) a_{mn} dq^m dq^n$. The laws of motion are discussed, leading to a generalisation of Bonnet's theorem on particle orbits and a geometrical elucidation of the Principle of Least Curvature. A completely determinate form of the Lagrangian equations for non-holonomic systems is developed. Necessary and sufficient conditions are obtained for the admissibility of $(N - 1)$ ignorable co-ordinates in a system with N degrees of freedom. From an invariant geometrical definition of stability three special types of particular dynamical importance are selected. A new definition of steady motion is given. The system of normals to a curve, originally defined by Blaschke, plays a fundamental part.—**P. E. Shaw** and **C. S. Jex**: Tribo-electricity and friction.—**H. G. de Laszlo**: The absorption-spectra of some naphthalene derivatives in vapour and solution. The ultra-violet absorption spectra of mono-derivatives of naphthalene containing the groups CH_3, Cl, Br, OH, COOH, CN, and NH_2, were measured in vapour and in hexane solution. The β-isomer spectra are more like that of naphthalene than the α spectra. All were shifted towards the red when compared with naphthalene by an amount which is of the same order in the case of naphthalene and benzene derivatives containing the same group. The solution spectra are always shifted towards the red when compared with the vapour. This shift varies with the group, suggesting a modified "Stark effect" when the dipolar molecules are in the strong electric field of the solvent. The bands of most of the bodies examined have been ranged in simple series. These periodicities, representing the atomic oscillations, are all smaller than that of the parent body and appear again in the infra-red.—**O. Maass** and **W. H. Barnes**: Some thermal constants of solid and liquid carbon dioxide.—**R. H. Fowler** and **D. R. Hartree**: An interpretation of the spectrum of ionised oxygen (O II). The terms of the O II spectrum deduced from the observed lines by A. Fowler are correlated with theoretical terms expected on the theory of complex spectra developed by Heisenberg and Hund. The general agreement is satisfactory. No lines involving the deepest-lying terms have yet been identified, but from consideration of the O I spectrum it appears likely that the normal term of the O II spectrum is a quartet *S* term.—**G. C. Simpson**: On lightning. The conducting channel of a lightning flash originates in the region of maximum electric field and develops only in the direction of the seat of negative electricity. A negatively charged cloud can only be discharged by a discharge originating in a positively charged cloud, or in the induced positive charge on the earth's surface. A positively charged cloud may be discharged by discharges starting in the cloud and terminating either in the surrounding air or on the earth's surface. If a lightning flash is branched, the branches are always directed towards the seat of negative electricity. The application of these conclusions to 442 photographs of lightning discharges reveals the fact that the majority of lower clouds from which discharges proceed are positively charged.

Geological Society, February 19.—**J. W. Evans**: Regions of compression (Anniversary address). The characteristic structures of regions of compression—folding, thrust-faulting and slaty cleavage—are, as a rule, the result of horizontal forces ultimately to be attributed to the contraction of the earth's interior as it cools. It has been doubted whether, with the energy released by radioactive elements, the earth cools at all. The whole of that energy, however, is not converted into heat; much must be employed in effecting physical, chemical, or atomic changes in the surrounding rock. Jeffreys shows that the contraction on cooling of the crystallised rocks is more than enough to account for the folding of existing mountains. But there are many folds of ancient mountains, now worn down, which would require still more contraction. This may have occurred in the following ways: (1) the contraction of uncrystallised magma retaining the volatile constituents is greater than that of crystallised rocks; (2) the contraction on crystallisation is equal to that on a big fall of temperature; (3) contraction may take place on changes of crystal-structure, chemical composition, or even atomic nature; (4) it will result from the loss of volatile constituents; and (5) it must follow on the increase of pressure in the earth's interior due to the slowing down of its rotation. On the other hand, the extent of the crust may be locally increased in periods of tension by (1) infilling of rifts by igneous intrusions, and (2) slip-faulting; and also by hydration of rocks. Compression and folding may also result (1) from change in the earth's form on diminished rotation; (2) from change in the position of the crust relatively to (*a*) the poles and equator, (*b*) the maximum of gravitational force. In illustration of the process of folding, two examples are described: (1) the 'Hercynian,' or 'Armorican,' folding of the south-western peninsula of England and south Wales; and (2) the Wealden folding between the Thames Valley and the 'Massif Central' of France.

Physical Society, February 26.—**J. E. Calthrop**: The effects of torsion upon the thermal and electrical conductivities of aluminium, with special reference to single crystals. An attempt has been made to find the changes produced by torsion in the conductivities of single aluminium crystals, and of the annealed and hard aluminium wires from which the crystals are prepared. The hard wire gave a decrease of a few parts in a thousand in the thermal conductivity, but no change greater than one part in 1000 has been found in crystal wires. The decreases in the electrical conductivities, of the order of a few parts in 10,000, appear to be almost the same for all specimens.—**T. H. Harrison**: A study of the concurrent variations in the thermionic and photo-electric emission from platinum and tungsten with the state of the surfaces of these metals. The thermionic and photo-electric work functions for the same specimens of tungsten and platinum depend greatly on the previous heat treatment of the material. For platinum the curves showing the dependence of photo-electric sensibility on the wave-length of the irradiation are of four different types, while as regards thermionic properties the specimens can take up either a 'large-emission' or a 'small-emission' state, according to their treatment. The photo-electric work function of platinum appears to be greater than the thermionic, but no definite results were obtained for tungsten. The photo-electric curves obtained for both metals extended asymptotically towards zero emission in the direction of increasing wave-length. The irregularities in behaviour are attributed to the state of the surface of the specimens.

Royal Statistical Society, March 16.—**Major P. G. Edge**: The growth of mortality due to motor vehicles in England and Wales, 1904-23. In 1904 171 deaths caused by motor traffic were recorded in England and Wales; by 1923 this figure had grown to 2414. During the period 1904-23, while the mortality rate due to all causes had diminished by more than 11 per cent., the mortality caused by motor traffic had increased by approximately 1000 per cent. In London the figures for 1904 and 1925 were 24 and 595 respectively. The general mortality rate in London was 30 per cent. lower in 1923 than in 1904, while motor fatalities increased by more than 2000 per cent. Motor-vans are responsible for more than their share of fatal accidents. Driving licences should only be issued after a serious test of proficiency, and vehicles should be compulsorily insured. Lack of road sense and responsibility are more frequent factors of accidents among commercial vehicles than among owner-drivers.

Official Publications Received.

Dacca University Bulletins. No. 4: Eastern Humanism; an Address delivered in the University of Dacca. By Prof. Sylvain Levi. Pp. 9. (Dacca: The University; London: Oxford University Press.) 8 annas; 8d.

The Engineer Directory and Buyers' Guide, 1926. Pp. 260. (London: 33 Norfolk Street, W.C.2.)

Calendario della Basilica Pontificia del Santissimo Rosario in Valle di Pompei per l' anno 1926. Pp. 240. (Valle di Pompei.)

Diary of Societies.

SATURDAY, APRIL 3.

SCOTTISH JUNIOR GAS ASSOCIATION (Annual Meeting) (at Royal Technical College, Glasgow), at 7.—Prof. T. Gray: Address.

TUESDAY, APRIL 6.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—W. J. Williams: Technical Education in relation to Industry.

WEDNESDAY, APRIL 7.

INSTITUTION OF AUTOMOBILE ENGINEERS (Derby Graduates' Meeting) (at Cavendish Café, Derby), at 7.30.—A. A. Rubbra: Problems of the High-speed Optical Indicator.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—H. Droop Richmond and J. A. Eggleston: The Analysis of Acetic Anhydride.—H. Droop Richmond and E. H. England: The Analysis of Glacial Acetic Acid.—Dr. J. F. Tocher: (a) Errors of Personal Judgment in Chemical Work; (b) Results of Further Work on Variations in the Composition of Milk.—E. R. Bolton and K. A. Williams: A Test for Tung Oil.

THURSDAY, APRIL 8.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—S. Mavor: The Applications of Machinery at the Coal Face.—L. Miller: The Design of Storage-Battery Locomotives for use in Coal Mines.—R. Nelson: Electricity in Mines: A Short Survey.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 6.30.—Marchese De Pinedo: A 35,000 Miles Flight.

INSTITUTION OF STRUCTURAL ENGINEERS, at 7.30.—E. S. Andrews: The Production of Structural Steel Sections.

OIL AND COLOUR CHEMISTS' ASSOCIATION (at 8 St. Martin's Place, W.C.), at 8.—Dr. A. P. Laurie: The Optical Properties of Linseed Oil.

SOCIETY OF DYERS AND COLOURISTS (Bradford Junior Branch).—C. O. Clark: The Proofing of Textiles against Insect Pests by means of Eulan.

FRIDAY, APRIL 9.

ROYAL SANITARY INSTITUTE (in Town Hall, Weston-super-Mare), at 11 A.M.—The Rôle of Different Agencies in the Improvement of the Milk Supply:—Dr. W. G. Savage: The Bacteriological Laboratory.—W. S. Stevens: The Veterinary Surgeon.—H. R. Day: The Milk Inspector.—J. W. Dallas: The Agricultural Institute.—P. B. Tustin: The Large Scale Distributor and the Consumer.

DIESEL ENGINE USERS' ASSOCIATION (at Caxton Hall), at 3.30.—W. A. Tookey: Industrial Tests on Internal Combustion Engines.

ROYAL ASTRONOMICAL SOCIETY, at 5.—J. M. Reesinck: Note on the Radiation of a Pulsating Star.—S. A. Mitchell and H. L. Alden: The Photometric Scale of the Leander McCormick Observatory.—(The late) E. E. Barnard: Visual Observations of the Brightness of Nova Persei No. 2 (Anderson 1901).—S. A. Mitchell and H. L. Alden: Observations of Nova Persei (1901) made with the 26-inch Refractor of the Leander McCormick Observatory.—Dr. J. K. Fotheringham: Precession, Galactic Rotation, and Equinox Correction.

INSTITUTE OF MARINE ENGINEERS, at 6.30.—Annual Meeting.

SOCIETY OF CHEMICAL INDUSTRY (Manchester Section) (Annual General Meeting) (at St. Mary's Parsonage, Manchester), at 7.—Prof. R. V. Wheeler: The Constitution of Coal.

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—S. Hazzledine Warren: The Preservation of Fragile Remains.—F. H. Worsfold: An Examination of the Contents of the Brick-Earths of Tankerton Bay, Kent.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—T. H. Dimbleby: Modern Methods of Cast Iron Pipe Manufacture.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Literary and Philosophical Society, Newcastle-upon-Tyne), at 7.30.—W. S. Burn: High Powered Oil Engines.

INSTITUTE OF METALS (Sheffield Section) (at Sheffield University), at 7.30.—R. T. Rolfe: Bronze.

PHILOLOGICAL SOCIETY (at University College), at 8.—English Dialect Society and Dictionary.

SATURDAY, APRIL 10.

MINING INSTITUTE OF SCOTLAND (at Glasgow).

INTERNATIONAL MEETING.

APRIL 16 TO 20.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY (Annual Meeting will be held in Czecho-Slovakia). (Particulars from Dr. E. P. Poulton, at 36 Devonshire Place, W.1.)

CONGRESS.

APRIL 2 TO 21.

JERUSALEM AND BEIRUT, INTERNATIONAL ARCHÆOLOGICAL CONGRESS.

SATURDAY, APRIL 10, 1926.

British Optical Science.

THE practice of optical science is largely concerned with the provision of means for aiding vision and increasing its effectiveness. Of the human senses, vision is the one on which, above all others, scientific work directly or indirectly depends for its successful prosecution. Thus, while optics may be regarded as the handmaiden of the other branches of science, the service rendered by it is essential and fundamental. It has provided science with—if we may quote the three classical examples—the microscope, without the aid of which medical science would have made little progress; the telescope, which has enabled astronomy to explore the heavens; and the spectroscope, which has played such a predominant part in modern physics and astrophysics.

With the increasing application of science and scientific methods to industrial processes, optical science has been brought more and more into the service of industry. It has efficiently fulfilled this service by reason of the fact that it has been able to provide not only delicate and powerful means of making observations, but also means of making accurate quantitative measurements in a simple and rapid manner. The use of the spectrometer in chemistry and the chemical industry, of the refractometer in biochemistry and in the preparation of foodstuffs, of the polarimeter in the evaluation of essential oils and in the sugar industry and of the interferometer in the examination of gases and liquids, are a few examples of such applications, which are generally distinguished by simplicity of manipulation and by the rapidity with which results can be obtained.

As the study of absorption spectra has progressed, the measurement of selective absorption has become of great practical importance to the chemist, and spectrophotometers are now in regular use which enable quantitative measurements to be made, not only in the visible spectrum, but also in the infra-red and in the ultra-violet. The modern colorimeter has provided means by which the analysis and specification of colour can be recorded numerically, and thus permits of the accurate reproduction of any colour without recourse to the instrument on which the analysis was actually made. The position occupied by the microscope as an instrument of control is so thoroughly appreciated that it need scarcely be mentioned. A casual study of the many papers that have been read at the meetings of the Industrial Applications Section of the Royal Microscopical Society is sufficient to make one realise the difficulty of specifying any industry of real importance which has not materially benefited by the use of the microscope. The application also of the camera and of optical projection methods in routine testing and in specific investigations in industry has now been definitely established.

A survey of the uses to which optical instruments have been put might be indefinitely extended. Not only in industry but also in astronomy and geodesy, in medicine and biology, in aviation and navigaton, in photometry and illumination, in education and entertainment, has optical science found wide and useful scope for the application of its products. Nor has it neglected the simpler appliances on which so many of us depend for overcoming the limitations of our unaided vision and enabling us to carry out our ordinary occupations with greater comfort and consequently with greater efficiency. There has been evidence of growing interest in the care and preservation of the eyesight, whether of the child, the adolescent, or the adult, and considerable attention has been directed to a study of the eye, more especially with regard to the mechanism and processes involved in the act of seeing. Improvements have been effected in the methods and apparatus for detecting and measuring errors of curvature and refraction of the eye, and, simultaneously, investigations have been conducted which have resulted in many important improvements in the form of the lenses applied to give the necessary correction.

The advances which have been made during recent years in the development and production of new types of optical instruments have been notable and far-reaching in their effects. On a previous occasion (NATURE, Aug. 22, 1925, pp. 265-267) we referred to the predominant share taken by British workers in aiding these advances and suggested that, in the interests of the optical industry, its achievements should be made more widely known. The forthcoming Optical Convention, which is to be held during the week April 12-17, should provide an opportunity for the technical and general public to obtain a comprehensive account of the important developments that have taken place in optical science and in the optical industry in Great Britain since the last Optical Convention in 1912.

At no time in the history of British optics has progress been more rapid than during this period, and evidence of this progress in the different branches of theoretical optics, in the varieties of optical instruments, and in the various applications of optical methods, should not be lacking. British optical products are of such variety that a thoroughly organised and descriptive exhibition of them should have a high educational as well as commercial value, and should prove of interest not only to the optical expert and to those engaged in scientific work in which optics is subservient to some other branch of science, but also to that large and ever-increasing body of regular users of optical instruments of various types who are yet uninstructed in the nature, construction, or origin of the instruments they use.

The invention of optical systems and the development and perfection of new instruments, during the period under review, have been accompanied by investigations into the fundamental scientific principles on which they are based, and results of considerable value have been published. Continuous investigations have been conducted, for example, in analytical geometrical optics, in refractometry, and in colour measurement at the National Physical Laboratory, Teddington, in physical optics and instrument design at the Imperial College of Science and Technology, London, and in ophthalmological optics at the Northampton Polytechnic Institute, London. Investigations of a fundamental nature, as well as those directed towards immediately practical ends, have also been conducted at the British Scientific Instrument Research Association, at various universities and colleges, and in the laboratories of several manufacturing firms in the optical industry. The full nature and extent of these investigations will no doubt be clearly indicated during the Convention, and also their influence, on one hand, on optical production, and, on the other, on the progress of related branches of science.

Papers dealing with the results of these investigations will be of interest mainly to those engaged professionally in optics or in the application of optics to some special science. The programme also includes, however, lectures addressed more particularly to the amateur, and discourses and demonstrations of such a character as to show the position of optics in the everyday life of the individual and of the nation. Thus, if the aims and objects of the Convention are even in part attained, there should result not only a much wider appreciation of the past achievements and current enterprise of the British optical industry and those associated with it, but also an appreciation of the part played by optical science in almost every sphere of human endeavour.

Agricultural Progress in the United States.

History of Agriculture in the Northern United States, 1620–1860. By Dr. Percy Wells Bidwell and Prof. John I. Falconer. (Publication No. 358.) Pp. xii+512. (Washington: Carnegie Institution, 1925.)

FROM the time of the Pilgrim Fathers in 1620 until the Civil War and the abolition of slavery in the middle of the last century, agriculture in the northern United States developed steadily from the smallest beginnings, progress being intimately associated with increasing colonisation and extension of occupied lands westward. In the present volume the authors have most ably presented the history of American agriculture up to the time that a radical change in the economic life of the nation was brought about by the Civil War. The account is one that will appeal to the general reader of history as well as to the agricultural worker; and, notwithstanding the wealth of detail, it captures the imagination and leaves a clear and forcible picture of the progress of agricultural development in the States.

The earliest settlers on the eastern seaboard found some land already cleared and abandoned by the Indians, and further rough clearance was made by burning woods and meadows. Maize was the chief grain crop from the beginning, and the primitive method of manuring was to insert two or three fishes in each hill of corn. Multiple cropping was practised with maize, peas, and pumpkins, and wheat did well when introduced until attacks of black-stem rust, about 1860, caused spring wheat to be abandoned in favour of autumn wheat. Stock was very scarce at the beginning, the initial difficulty being shortage of forage, the native grasses not being sufficiently nutritious. The rapid spread of introduced English grasses and clovers improved matters, and islands were largely utilised for pasturage, as the common field system of agriculture precluded grazing for much of the year. The introduction of sheep was encouraged by legislation, especially in New England, and though horses were also brought in, oxen were preferred for most farm work for almost two hundred years longer. The earliest New England farms were very small, only about 13 to 38 acres, which was rather surprising considering the cheapness of land. Lack of capital was the difficulty, and this was reflected in the scarcity of livestock and food supplies and the poverty of farm tools and implements, even ploughs being missing at first, the work being done by mattocks and hoes. The first beginnings of trade in agricultural products were to relieve the food shortage, but eventually trade between the West Indies and New England was a central feature of economic life. New England supplied general agricultural necessities to specialised sugar-planting islands which could not afford time or labour for producing them. Export of horses and salted meat began about 1650, and continued until the end of the eighteenth century. Boston, Philadelphia, and New York became the chief centres for internal trade in farm products.

Various systems of land tenure and distribution were adopted by different colonies, but the fundamental economic condition behind them all was the abundance of cheap land, which made both large estates and tenancy impossible. New England adopted community settlements, and common fields survived in pastures long after tillage fields had been separately enclosed. The system in the middle colonies was that of settlement by the individual and payment by quitrents, which were practically unknown in New England.

During the eighteenth century two types of agriculture existed, that of pioneering in new settlements on the frontier, steadily advancing to the west, and that of the older agricultural communities on the seacoast. The continual grain cropping and general lack of manuring caused much land soon to become 'worn out,' and westward migration in search of more fertile areas became general. Nevertheless, the value of land in the eastern colonies rose rapidly, and land speculation became rife. As time went on the land systems put into force in the different States opened up affected the relative colonisation and, except in New York State, the settlement of back country was favoured. Emigration west was also partly influenced by a growing desire to escape from the puritanical social and ecclesiastical systems common in early settlements. The pioneers cleared land by girdling or burning, followed by two years' grain crops and then grass. The life was extremely hard, but resulted in great increase in the capital value of the holdings even when incomes were small. Lumbering, potash, and maple sugar-making were subsidiary industries in suitable districts.

About 1780 the poorness of the farming was noteworthy, rapid deterioration of land being caused by lack of rotation crops. Successive unmanured grain crops were taken until the land was exhausted, when it was allowed to become covered with grass and bushes for several years until it was considered sufficiently rested to produce more grain. This system of weed fallowing for renewal of fertility was gradually replaced by sowing down artificial meadows, as the stock increased beyond the capacity of natural pasturage. Some manures, as seaweed, gypsum, and limestone, came slowly into use after 1750, and rotations were introduced. Maize held its position as the chief grain crop, the total produce being more than all other cereals together. The association of wheat rust with the barberry was soon recognised, and legislation against the shrub was in force so early as 1726 in Connecticut.

The colonial farms, throughout the eighteenth century, were almost entirely self-contained, providing food, clothing, and housing for their occupiers; salt, molasses, rum, tea, and coffee being almost the only goods habitually bought. Farmers on the coast were often sailors or fishermen as well, and inland farmers were often artisans. The lack of a home market was the insuperable barrier to specialisation in farming and prevented progress, in inland towns especially. Export trade to Europe grew towards the close of the eighteenth century, but that to the West Indies remained the most important, $1\frac{1}{2}$ million bushels of maize being exported thereto in 1792, and more than 1 million bushels of wheat.

The first forty years of the nineteenth century marked a period of expansion and progress, as the population rapidly increased with a westward movement. The government federal land policy favoured settlement, giving liberal political privileges and freedom from tariff restrictions to new settlers. West of the Alleghanies the richer land gave better crops and pasturage, but all the early western settlements were extensive in nature, little labour and capital being expended over large areas, production being chiefly for home consumption until such time as markets were opened up. The gradual development of internal western trade with an eastern market for livestock was of great significance in American economic and political history. At the end of the eighteenth century definite interest in agricultural improvement was aroused, and the first agricultural society was founded in Philadelphia in 1785; others followed, and were pioneers in agricultural education.

In 1807 one Elkanah Watson exhibited two merino sheep at Pittsfield, Massachusetts, thus founding the cattle shows or fairs in the United States, making the direct appeal to farmers which the agricultural societies had failed to do. State aid was forthcoming, and a chair including agriculture was founded at Columbia University, while at Gardiner, Maine, the first institute for teaching farming only was opened in 1822. The Agricultural College, however, was founded considerably later, in 1857, at Michigan. During this period also many types of labour-saving machines were introduced, aiding progress still further. Wool growing on a commercial basis began to develop in a spectacular way in the eastern States, nineteen million sheep being grown in 1840, and general improvement and specialisation of livestock took place, with the introduction of special breeding stock from abroad. Throughout the colonies a gradual transition was taking place from self-sufficient economy to commercial agriculture, the chief hindrance being lack of working capital and imperfect organisation of markets. The most significant change was the decline in household industries, with the transfer of textile industries from farm-house to factory.

After 1840 a period of transformation set in, which is dealt with very fully by our authors. The development of prairie agriculture in the west, with rapid settlement and soil exploitation, the building of canals, roads, and railways, thus giving access to new markets, caused readjustment of eastern farming to meet western competition, while the advance in agricultural chemistry made possible the era of artificial fertilisers. By 1860 the increase in corn production and stock rearing had pushed steadily westwards, while hay was the leading crop in the east, where dairy farming had grown steadily in importance.

The situation at the close of the period under consideration may best be indicated by a quotation:

> "Whenever a branch of agricultural production, such as wheat, wool, or beef, proved profitable in the west and poured its supplies into the eastern market, it became necessary for the eastern farmer to find some other line of development; and, fortunately for the eastern farmer, the development of an urban population made this possible. The uncertainty in the choice of farm enterprises was stimulating to thought. It tended to make the agriculture of the period rational rather than traditional. It stimulated the development of the agricultural press and paved the way for the establishment of agricultural education."

W. E. B.

Crystals and Chemistry.

Crystalline Form and Chemical Constitution. By Dr. A. E. H. Tutton. Pp. xii+252. (London: Macmillan and Co., Ltd., 1926.) 10*s*. 6*d*. net.

Time was when the crystal was emblematic of the mysterious and the supernatural; the regularity and beauty of its outward form inspired the belief that it possessed properties which placed it on a different plane from ordinary matter. Science has discredited the superstition but has really emphasised the wonder and the mystery. That the regularity of form implied a corresponding regularity in elemental structure was early recognised, and many and varied have been the attempts to explain the nature of a crystal in terms of the properties of the chemical molecules of which it is composed. Of recent years the subject has received fresh attention chiefly because the discovery of X-rays has placed in the hands of the physicist a new tool which enables him to probe beneath the surface and actually to examine the arrangements and dispositions of the atoms or molecules in the small unit of pattern, the continued repetition of which finally results in the familiar crystal. The widespread and continually expanding applications of X-rays to the problems of crystallography have perhaps resulted in a tendency to ignore the results of previous work, and a book such as this will perhaps do something to emphasise the immense volume of results accumulated by the pure crystallographers, results which have perhaps not always had the recognition they merit.

The book contains the subject matter of a series of lectures and is, in a way, an abstract of some of the material dealt with more fully in the author's larger and well-known text-book. The title is a somewhat comprehensive one, and it is not to be expected that the whole of the field it implies can be covered in a relatively small volume. Dr. Tutton's own researches form the bulk of the material on which the deductions are based. These are, for the greater part, concerned with some remarkable isomorphous series, the alkali sulphates and selenates and the corresponding double sulphates and selenates. For the satisfactory examination of the small variations in structure of the members of such series, the author was forced to devise new and more accurate methods of measurement, and one chapter is devoted to a description of some of the elaborate and ingenious instruments designed especially for this work.

In the succeeding chapters are given the results of these investigations, results which once more demonstrate that an increase of knowledge almost always results from an increased precision of measurement. The author emphasises the fact that, although there is a very close resemblance between the various members of these series, there are differences and these differences are subject to very definite laws. For example, when potassium is replaced successively by rubidium and cæsium, all the properties of the crystal show progressive changes; rubidium is always intermediate between potassium and cæsium, no matter whether it is the dimensions or angles of the crystal unit, the refractive indices, the heat expansion, or some other property which is being measured. In the same way, it is always found that the ammonium salt resembles extremely closely that of rubidium, implying that a replacement of the rubidium atom by the NH_4 group can be effected with practically no change in the crystal properties.

In the latter half of the book various interesting problems are discussed, problems which are for the most part suggested by the researches on isomorphous series. There Dr. Tutton describes the conditions which favour the growth of crystals of one substance on the surface of another and the formation and nature of mixed crystals. Further chapters are devoted to the questions of enantiomorphism and optical activity and to that interesting phenomenon, the liquid crystal.

A brief survey is given of Federov's methods of crystal classification and description, and in directing attention to this work the author has performed a real service. To one accustomed to the usual method of crystal description, Federov's papers make difficult reading, but the signs are not wanting that there is a real physical significance in the notation and that, in many cases, the description of a crystal in the way advocated by Federov gives a valuable clue to the molecular arrangements.

Throughout the volume the author frequently refers to the results of X-ray measurements, but has made no attempt to give a full account of this work. His aim has rather been to show how it has confirmed and extended the deductions made by the older methods. This does not mean that he does not appreciate the X-ray work; in fact, in his enthusiasm for it, he is apt at times to take as an established fact what the X-ray worker intended only as a speculative suggestion.

The book is admirably produced and profusely illustrated by excellent diagrams and plates, and is completed by a bibliography of the author's researches and a detailed index. It is perhaps a pity that no references are given to the many other researches described throughout the volume.

Osteology of the Reptiles.

The Osteology of the Reptiles. By Prof. Samuel Wendell Williston. Arranged and edited by Prof. William King Gregory. Pp. xiii + 300. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1925.) 18s. 6d. net.

IN no domain of zoological science have the contributions of American naturalists been more splendid than in that of vertebrate palæontology, and in the list of pioneer workers in this domain an honoured place will always be accorded to Samuel Wendell Williston, who, born and nurtured in obscurity, had by the time of his death in 1918 won his way to recognition as the chief authority upon the extinct amphibians and reptiles. Apart from his specialist papers upon fossil vertebrates and upon modern dipterous flies, Williston was well known to the general zoologist for his excellent book on "Water Reptiles of the Past and Present," published in 1914, and during the last year of his life he was busily engaged in the preparation of a second work of a general character on "The Reptiles of the World, Recent and Fossil." The volume now under review comprises the main part of this general work, so far as it had been completed at the time of the author's death, put into shape and edited at the competent hands of Prof. W. K. Gregory.

The book is one which will be of great use to the student and teacher of osteology, while to the general zoologist it will serve the useful purpose of providing a conspectus of contemporary knowledge regarding the bony skeleton of extinct reptiles, drawn up by a master of the subject.

Perhaps the most valuable part of the book consists of the series of illustrations, nearly two hundred in number. These are for the most part line drawings by the author, embodying the latest results of palæontological research whether by himself or by others, and of admirable clarity. While these drawings take up a large part of the whole volume, they are accompanied by clear and valuable letterpress—interrupted here and there by gaps still unfilled when the author finally laid down his pen. The weakest parts of the book are to be found, as in many other palæontological works, where the author strays beyond the confines of osteology into the field of general evolutionary theory. Such old friends as "evolution is irreversible," "there has been a continuous loss of parts" (in the evolutionary history of the bones of the skull), "a race of small animals has never been evolved from a race of large animals," had better be omitted in the text-books of to-day. They are in conflict with one of the main canons of evolutionary philosophy—that its principles must be founded upon a broad basis in which are incorporated the available facts not of palæontology alone but of comparative anatomy, embryology, physiology, and field natural history as well.

In practice such statements do harm; for the student, his attention gripped in the first instance and his interest fired by such clearly and crisply enunciated 'laws,' is bound sooner or later—if he passes into territories other than those of fossil osteology—to come across facts which raise doubts in his mind as to whether there is anything in such so-called laws. He finds, for example, the facts of embryology assuring him that the early evolution of the Amniota has as one of its characteristic features the gradual increase in the size of the egg correlated with the provision of a larger and larger amount of hoarded-up food material or yolk, and that on the other hand the evolution of the modern mammal has involved a reversal of this evolutionary process—the supply of food yolk being gradually reduced and the egg reverting to a comparatively small size. He is assured again that the evolution of the modern fishes has involved the primitively symmetrical pointed tail passing through a period of gradually increasing asymmetry, but that at a later period the evolutionary history of various highly specialised modern teleosts has involved a reversion to the symmetrical pointed form of tail. He learns that in the evolutionary history of the cranial bones, reduction in number of elements by processes of fusion rather than of elimination are by no means to be ignored. He realises that although it is perfectly true that increase in size of body has been one of the principal features of animal evolution, there are yet very numerous cases where adaptation to a particular mode of life has involved great diminution of size.

However, such little aberrations, as I regard them, into unsound evolutionary philosophy must not be allowed to distract our attention from the main fact that this last book by Samuel Wendell Williston is, as regards what it purports to be—a text-book on the osteology of the reptiles—of admirable quality and great value.

J. Graham Kerr.

Enzyme Action.

Die Fermente und ihre Wirkungen. Von Prof. Dr. Carl Oppenheimer. Nebst einem Sonderkapitel: *Physikalische Chemie und Kinetik*, von Dr. Richard Kuhn. Fünfte völlig neu bearbeitete Auflage. Lief. 1-8. Pp. 1204. (Leipzig: Georg Thieme, 1925.)

PROBABLY all the important chemical actions operative in animal and vegetable systems take place through the agency of enzymes or ferments, the organised catalysts.

It is somewhat unfortunate that the difficulties attending the preparation and purification of enzymes are so great that the chemical composition of any one of a very numerous family is still unknown. Even Willstätter's preparations in a high state of purity contained both proteins and carbohydrates in variable quantities. Many attempts dating from the time of Liebig have been made to elucidate their mode of operation, and to obtain from an examination of the physical and chemical processes of enzyme action some idea of their chemical constitution and structure. The evidence in favour of the hypothesis that enzymes exert their catalytic properties by a process of adsorption, similar in some respects at least to the inorganic catalysts, appears to be complete, but the nature of the adsorption complexes is unknown. It is frequently argued that since enzyme action is even more selective in action than is the case with inorganic catalysts, the adsorbate-substrate union must be highly complex. We find the view fully expressed that enzymes may be regarded as proteins, globulin-like in character, the union to the adsorbate being effected by reactive groups which occur at definite space intervals along the complex molecule. The selective action of hydrolytic enzymes for optically active adsorbates lends support to the multipoint contact or 'key in lock' hypothesis, but, as in the case of simple inorganic hydrolysis, the effect of steric hindrance on one reactive group and on the reaction velocity is a factor which cannot be left out of consideration.

It is fully established that enzymes are very sensitive to a change in hydrogen ion concentration of their environment, supporting the view that they are amphoteric substances possessing diverse activities in their different ionic modifications. At the same time, the enzymes are colloidal in their nature and their activity is greatly dependent on the degree of dispersion, which in turn is affected by numerous factors such as alteration in the protein content of the solution which serves to support or protect the enzyme, the presence of electrolytes, alteration in temperature or intensity of incident radiation.

The fifth edition of Prof. Oppenheimer's "Die

Fermente und ihre Wirkungen" must be considered as the most authoritative work that has yet appeared on this subject. A casual glimpse of the various volumes, of which eight have now appeared, indicates that a veritable "Beilstein" of information has been collected together. A closer inspection reveals the fact that the vast mass of experimental data has been carefully assimilated and subjected to a critical examination. The alternative points of view of various investigators have been given without bias.

The book may be divided into three parts. In the first the chemical and physico-chemical characteristics of enzyme action are discussed in detail. Nearly three hundred pages of text, plentifully supplied with diagrams, experimental data, and references which appear completed up to and including the year 1924, have been written by Dr. Richard Kuhn on the physical chemistry of enzyme action, forming in itself a monograph which is not only a mine of information but also a model of condensation and clarity.

A short section is devoted to a discussion on the biology of ferments, whilst the remainder of the work includes a systematic classification of various types of ferment and enzyme action.

The production of this work is an achievement on which both Dr. Oppenheimer and Dr. Kuhn as well as the publishers, G. Thieme of Leipzig, are to be congratulated; for, if it accomplished no more than to serve as a digest of the enormous quantity of work that has appeared during the last decade alone, and published in the most diverse periodicals, on this complicated subject, it would have been of great value. Presenting in addition a careful formulation of the considered views of those who have made a detailed study of enzyme action, the volumes may well be considered indispensable to those interested in the subjects of chemistry and physics in their biological application.

E. K. Rideal.

Our Bookshelf.

Dr. H. G. Bronn's Klassen und Ordnungen des Tierreichs wissenschaftlich dargestellt in Wort und Bild. Sechster Band, Abteilung 1: *Pisces* (*Fische*). Bearbeitet von Prof. Dr. M. Rauther. Lieferung 39. Pp. 583-710 + v. 15 gold marks. Fünfter Band: *Arthropoda.* Abteilung 2: *Myriapoda.* Bearbeitet von Dr. K. W. Verhoeff. Lieferung 100. Pp. 539-666. 14·50 gold marks. Dritter Band: *Mollusca* (*Weichtiere*). Buch 2: *Pulmonata.* Bearbeitet von Dr. H. Simroth, fortgefuhrt von Dr. H. Hoffman. Lieferung 147. Pp. 737-832. 10·50 gold marks. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1924–25.)

Band 6, Abteilung 1 contains accounts of the Leptocardii and the cyclostomes contributed by four successive authors—Drs. Lònnberg, Favaro, Mozejko, and Rauther, the last named being responsible for this Lieferung 39 which completes the Abteilung. He has contributed the last dozen pages of the description of the urinogenital organs of cyclostomes, a clear account of the development and organogeny of Lampetra and of Bdellostoma and of the biology of the principal species, and a scheme of classification in which the characters of the known genera and species are concisely stated. A short discussion on variation and similar matters, some general observations on geographical distribution, and an appendix on the origin and relationships of cyclostomes, form the concluding part of the text. There is an adequate systematic and subject index. Opportunity might have been taken to refer in the appendix to memoirs by Cole and others which have been issued since the earlier parts of the volume were published.

Lieferung 100 (Band 5, Abt. 2) opens with an account of the systematic characters of the Geophilomorpha, the families, subfamilies, genera, and subgenera being concisely defined and tabular keys provided where necessary. Supplements on the Scolopendromorpha, Lithobiomorpha, and Notostigmophora—two suborders and a subclass which were dealt with in preceding sections of the work—bring the information on these up-to-date. A concluding chapter is devoted to a detailed consideration of the geographical distribution of the Myriapoda, including the delimitation of the European and Mediterranean subregions, and a comparison of the chilopod fauna of the eastern and western parts of the latter.

Lieferungen 95-146 of Band 3, Buch 2, were written by the late Prof. H. Simroth and published in 1908–14. The first fifteen pages of the present Lieferung (147) are from his manuscript, and complete the account of the development of the reproductive organs of the Pulmonata, and summarise the records of natural and artificially produced developmental abnormalities. Dr. Hoffmann is the author of the rest of the Lieferung. He contributes a list of some 750 works published subsequent to 1908, which forms a continuation of the lists given in earlier parts of the book. A number of memoirs dealing with Indian and other species seem to have escaped attention and are not included in the list. The remaining pages contain appendices which embody the results of work published during the last twelve years. References are given to the earlier pages of the book to which these supplementary accounts relate; *e.g.* on the form of the body, shell, and operculum, on the integument, connective tissue, muscle, mantle, and on secretion of the shell.

Faune de France. Par L. Berland. 10: *Hyménoptères vespiformes, I.* (*Sphegidæ, Pompilidæ, Scoliidæ, Sapygidæ, Mutillidæ*). (Fédération française des Sociétés de Sciences naturelles: Office central de Faunistique.) Pp. viii + 364. (Paris: Paul Lechevalier, 1925.) 45 francs.

The author of this volume includes in the Vespiformes all wasp-like Aculeates other than the Chrysididæ. The present contribution deals with the five families Sphegidæ, Pompilidæ, Scoliidæ, Sapygidæ, and Mutillidæ, or, in other words, the fossorial forms. Owing principally to insufficiency of reference material, the Bethylidæ are not included, and their treatment is postponed until the appearance of a second volume which is in course of preparation. M. Berland has, for the first time, provided a comprehensive account of the 450 species of French fossorial wasps, and has accomplished his task with notable success. As in previous volumes of the series, full use is made of generic and specific keys, while each genus and species is also separately diagnosed. Under every species there is given a résumé of its distribution and of the chief facts relating to its biology. The biological notes are especially useful, since the author has sifted the literature of the subject with very evident care, and we know of no other work where similar information is available in an equally concise form. As M. Berland remarks, the study of the habits of Hymenoptera is more especially due to French observers, among whom the names of Latreille, Lepeletier, Dufour, Fabre, and Ferton are recalled. The author has wisely dispensed with long detailed lists of synonymy, and has left those who are curious on this subject to refer to the catalogue of Dalla Torre for all questions of nomenclature prior to 1897.

The book is profusely illustrated with 663 text figures, and, with the exception of Figs. 17-19 and 305, all are the original work of M. Berland. The various structural details which are thus represented add materially to the value of the book, and although many of these illustrations appear somewhat wooden in character, they nevertheless fulfil their purpose. We can recommend the book as one which should find a place on the shelves of English entomologists. A. D. I.

(1) *The Animals of New Zealand: an Account of the Dominion's Air-breathing Vertebrates.* By Capt. F. W. Hutton and James Drummond. Fourth edition, revised and enlarged. Pp. 434. (Auckland, Christchurch, Dunedin, Wellington, Melbourne and London: Whitcombe and Tombs, 1923.) 15*s*.

(2) *A Synopsis of the Vertebrate Animals of Tasmania.* By Clive E. Lord and H. H. Scott. Pp. v+340+41 plates. (Hobart: Oldham, Beddome and Meredith, 1924.) n.p.

(3) *Red Deer Stalking in New Zealand.* By T. E. Donne. Pp. xii+270+32 plates. (London, Bombay and Sydney: Constable and Co., Ltd., 1924.) 21*s*. net.

(1) IT is with pleasure that we welcome a new edition of Hutton and Drummond's "Animals of New Zealand." This is a well-written and well-illustrated account of a most interesting fauna, indispensable to all concerned with the vertebrate life of the southern hemisphere. It should do much to stimulate local interest and so help those who are endeavouring to preserve the fauna and flora of the Dominion.

(2) Mr. Lord and Mr. Scott are to be commended for their "Synopsis of the Vertebrate Animals of Tasmania." This work gives a concise account of all the vertebrates known to inhabit the island and the surrounding seas. Its illustrations are satisfactory and the volume contains a great deal of valuable information concerning the habits and distribution of many species. Some useful notes on mammalian osteology are incorporated in the text. Incidentally, here and there, the authors tell a good story, and that relating to the Hobart policeman who tried to arrest a sea-leopard, in the small hours, as 'a drunk and incapable,' is particularly pleasing.

(3) Though "Red Deer Stalking in New Zealand" is naturally a book for the sportsman rather than the zoologist, the latter will find in it a good deal of information relating to the present status of the red deer and of the many other species of deer that have now been introduced and acclimatised in New Zealand. Some very good photographs of heads from the Dominion, accompanied by measurements, add materially to the interest of the book.

A List of British Aphides (including Notes on their Synonymy, their recorded Distribution and Food Plants in Britain, and a Food-Plant Index). By Dr. J. Davidson. (The Rothamsted Monographs on Agricultural Science.) Pp. xi+176. (London: Longmans, Green and Co., 1925.) 12*s*. 6*d*. net.

THE volume under notice is the fourth of the recently instituted series of "Rothamsted Monographs on Agricultural Science," and is the first to treat of an entomological subject. The morphological characters separating allied species of aphides are often comparatively trivial, and this fact, coupled with polymorphism and a certain plasticity of host-selection, has led to much confusion in the identification of these insects. Their involved nomenclature has been badly in need of revision, and in many cases it has become a difficult task for the entomologist, who was not a professed aphidologist, to make certain of the genus or species to which a given name is strictly applicable.

Since the 'List' before us is a product of the activities of the Rothamsted Experimental Station, its object is more especially to facilitate the labours of workers in agricultural science. From this aspect only (even if there were no other) the accurate determination of species of aphides is of particular importance. This fact has in recent years acquired additional significance owing to the discovery that certain species of aphides, and apparently no others, are concerned with the transmission of mosaic disease in the case of the raspberry, tomato, potato, and sugar-cane. Dr. Davidson has done a useful service in providing synonymic lists of all the British species and genera of aphides in the light of recent taxonomic changes. The specific names are alphabetically arranged and amount to nearly 400, and the number of genera recognised is 87. The long list of plant genera and species, with the aphides recorded from them, should prove especially helpful. The first clue to the possible identity of a particular species of aphid is commonly obtained by noting, in the first instance, the plant upon which it is found. The book concludes with an extensive bibliography of all the more important papers on these insects.

Exercises in Practical Physics. By Sir Arthur Schuster and Prof. C. H. Lees. Fifth edition, revised. Pp. ix+373. (Cambridge: At the University Press, 1925.) 12*s*. 6*d*. net.

IT is some twenty-five years since the first edition of this book was reviewed in these columns. In several subsequent editions, including the present one, it has undergone some revision, chiefly necessitated by the steadily rising standard of the courses for which it was intended. It is a long life for any physics text-book, and such longevity is in itself the most eloquent of tributes to its many merits. Yet there may be some who will find lingering about it a suggestion of an old-world atmosphere, as it were, which a modern interpolation or two (the thermionic valve, for example) merely emphasises instead of dispelling. Still, it is difficult to support such an accusation—if it be an accusation—by specific instances. What is indisputable, on the other hand, is the admirable soundness and thoroughness which characterise the book throughout. Of particular value is its insistence on the consideration of order of accuracy of measurements and results, for this is an aspect of laboratory instruction which is apt to suffer nowadays from the congested condition of practical syllabuses. Students who work conscientiously through this book, even without assistance from a teacher, will have laid a very secure foundation for more advanced experimental work in physics.

At the same time, one cannot but wish that the scope had been more comprehensive. It is true that there are sufficient experiments to constitute a satisfactory course, but no two teachers would be likely to select exactly the same experiments as being best suited to their special circumstances, and the book would therefore have been much more generally useful had it contained a wider range of experiments, from which selection could be made as required.

Zoologie im Grundriss. Von Prof. Dr. Walter Stempell. Erste Lieferung. Pp. xviii + 160. 6·60 gold marks. Zweite Lieferung. Pp. 161-336. 6·90 gold marks. (Berlin: Gebrüder Borntraeger, 1925.)

THESE two parts are devoted to accounts of the morphology, structure, and classification of animals from Protozoa to Chordata, and the author has been faced with the problem of what to include and what to omit—as are all writers of text-books, and each author has his own views on the subject. But is seems difficult to justify the inclusion of even short accounts of relatively rare parasites of man, the affinities of some of which (*e.g.* Rhinosporidium, the Spirochætes, and the Chlamydozoa) with the Protozoa are more than doubtful. The brief description and single figure of the Mesozoa can be of little use, and the same may be said of the characterisations in two or three lines of many of the families of cœlenterates and other Metazoa. It is evident the author has carefully rationed himself in his descriptions of the more important organisms in regard to many of which further detail would have been helpful. The extent of the compression may be judged by citing as examples the Prototracheata, which are dealt with in 20 lines of text and 4 figures, the Scyphozoa in 30 lines and 5 figures, the rotifers in 26 lines and 2 figures, the Diptera in 15 lines and 4 figures; there are short descriptive legends to most of the figures.

The parts on the Mollusca and the Chordata are, on the whole, more satisfactory. The illustrations are usually well chosen and well reproduced, and many of them are original. It should have been possible to give better figures of Entamœba, the Spirochætes, the larva of Filaria and *Pulex irritans.*

The table of contents shows that the succeeding parts are to deal with physiology, development, biology, distribution, and phylogeny, on which there is room for a good text-book. We shall look forward with interest to the author's mode of treatment of these important subjects.

Ostwald-Luther Hand- und Hilfsbuch zur Ausführung physikochemischer Messungen. Herausgegeben von C. Drucker. Vierte neubearbeitete Auflage. Pp. xx + 814 + 3 Tafeln. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1925.) 35 gold marks.

OSTWALD'S "Hand- und Hilfsbuch" has changed almost beyond recognition since it was first issued in 1893. It was then a comparatively small book, and the reviewer remembers vividly how as a student he used it as a text-book of scientific German. The second edition, issued in 1902, called for the services of a collaborator in the person of Prof. Luther; and now, fifteen years after the appearance of the third edition, the issue by Prof. Drucker of a fourth edition has only been possible with the aid of a long list of collaborators, who have contributed complete sections on optical measurements, X-ray measurements, radioactive measurements, etc. Including the indexes, the whole volume now covers more than 800 pages, and it would have been still larger but for the fact that, in the opinion of the responsible editor, the appearance of the "Kolloidchemische Praktikum" of Wo. Ostwald has rendered it no longer necessary to add a section on the technique of colloid chemistry. In the same way the revision of the "Physikalisch-Chemischen Tabellen" of Roth and Scheel has made it possible to omit most of the numerical data. The details of the practical course at Leipzig (which includes fourteen electrical exercises, but only one optical experiment, with a sodium lamp as the only light-source) have, however, been retained as an appendix.

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof. Dr. Emil Abderhalden. Lieferung 173. Abt. 9: *Methoden zur Erforschung der Leistung des tierischen Organismus,* Teil 2, 1 Hälfte, Heft 2. *Methoden der Süsswasserbiologie.* Pp. 285-542. (Berlin und Wien: Urban und Schwarzenberg, 1925.) 10·80 gold marks.

THE second part of the "Methoden der Süsswasserbiologie" is a further instalment of that indispensable work "Handbuch der biologischen Arbeitsmethoden," edited by Prof. Emil Abderhalden, and continues the description of freshwater biological methods begun in Part 115. The present portion begins with the rearing of freshwater insects of all groups, followed by other invertebrates. In such experimental work, the knowledge of the food required by the animals in question is essential, and a large amount of exact information is given as to the feeding at every stage. The culture of certain invertebrates as fish food has now become a matter of extreme importance, and special prominence is given to the small crustacea such as the Cladocera, a separate chapter being given to *Daphnia magna* Straus. Then follow a long treatise on the rearing of freshwater fishes, more especially carp and trout, although others are also mentioned; a most interesting account of the methods of investigating the history of lake bottoms by means of samples taken by boring tubes and tube sounding leads; and finally chapters on boats for scientific work in inland lakes and a description of the working of the biological station at Lunz in the Austrian Alps. As each section is by an expert in his own line, we have an up-to-date account of all recent research methods which is of inestimable value to all freshwater biologists.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Motion of the Spinning Electron.

IN a letter published in NATURE of February 20, p. 264, Messrs. Uhlenbeck and Goudsmit have shown how great difficulties which atomic theory had met in the attempt to explain spectral structure and Zeeman effects, can be avoided by using the idea of the spinning electron. Although their theory is in complete qualitative agreement with observation, it involved an apparent quantitative discrepancy. The value of the precession of the spin axis in an external magnetic field required to account for Zeeman effects seemed to lead to doublet separations twice those which are observed. This discrepancy, however, disappears when the kinematical problem concerned is examined more closely from the point of view of the theory of relativity.

As usual, letters in heavy type will denote vectors. The anomalous Zeeman effect seems to require that the spin axis of the electron precesses about an external magnetic field $\mathbf{H}$ with angular velocity

$$\frac{e}{mc}\mathbf{H}, \quad . \quad . \quad . \quad . \quad (A)$$

where c is the velocity of light and $-e$, m are the electronic charge and mass. Suppose such a spinning electron moves with velocity $\mathbf{v}$ through electric field $\mathbf{E}$. At first sight it would seem that, being subject to magnetic field

$$\mathbf{H}=\frac{1}{c}[\mathbf{E}\times\mathbf{v}],$$

the spin axis will precess about the instantaneous normal to the orbital plane with angular velocity

$$\frac{e}{mc^2}[\mathbf{E}\times\mathbf{v}]. \quad . \quad . \quad . \quad . \quad (B)$$

As the mean value of this expression is just twice the angular velocity with which the perihelion of the orbit rotates on account of the variation of mass of the electron, this would lead to twice the observed doublet separation.

There is, however, an error in the above reasoning; the precession of the spin axis so calculated is its precession in a system of co-ordinates (2) in which the centre of the electron is momentarily at rest. System (2) is obtained from system (1), in which the electron is moving and the nucleus at rest, by a Lorentz transformation with velocity $\mathbf{v}$. If the acceleration of the electron is $\mathbf{f}$, and system (3) is obtained from system (1) by a Lorentz transformation with velocity $\mathbf{v}+\mathbf{f}dt$, then the precession which an observer at rest with respect to the nucleus would observe, and which should be summed to give the secular precession, is that precession which would turn the direction of the spin axis at time t in (2) into its direction at time $t+dt$ in (3) if both directions were regarded as directions in (1). To a first approximation system (3) is obtained from system (2) by a Lorentz transformation with velocity $\mathbf{f}dt$ together with a rotation $(1/2c^2)[\mathbf{v}\times\mathbf{f}]dt$. Thus the observed rate of precession will be, to a first approximation,

$$\frac{e}{mc^2}[\mathbf{E}\times\mathbf{v}]-\frac{1}{2c^2}[\mathbf{v}\times\mathbf{f}].$$

To a first approximation

$$\mathbf{f}=-\frac{e}{m}\mathbf{E},$$

so the rate of precession is

$$\frac{e}{2mc^2}[\mathbf{E}\times\mathbf{v}], \quad . \quad . \quad . \quad . \quad (C)$$

just half the expression (B).

The interpretation of the fine structure of the hydrogen lines proposed by Messrs Uhlenbeck and Goudsmit now no longer involves any discrepancy. In fact, as Dr. Pauli and Dr. Heisenberg have kindly communicated in letters to Prof. Bohr, it seems possible to treat the doublet separation as well as the anomalous Zeeman effect rigorously on the basis of the new quantum mechanics. The result seems to be full agreement with experiment when the calculation is based on formulæ (A) and (C).

I hope in a later paper to develop the above kinematical argument in greater detail.

In conclusion, I wish to express my appreciation of the encouragement and help of Prof. Bohr and Dr. Kramers.

Genes and Linkage Groups in Genetics.

NOW that Prof. MacBride has delivered himself of his final reply to Prof. Huxley on the subject of linkage and genes, I should like to offer a few comments on a point from which further confusion might easily arise in the future. It concerns the use of the word 'linkage.' This term was originally proposed by Prof. Morgan, and the first evidence of its appearance in print that I have been able to find is in the title of a paper published in the *Biological Bulletin* for August 1912 by T. H. Morgan and Clara S. Lynch on "The linkage of two factors in Drosophila that are not sex-linked." In the previous year Mr. Bateson and I had shown that what we had hitherto termed 'coupling' and 'repulsion' were in reality phases of the same phenomenon, and we subsequently adopted Morgan's term as a convenient one for the phenomenon as a whole. In this matter the United States and Europe saw eye to eye, and henceforward the term 'linkage' in this definite and precise sense has been in use by geneticists all the world over.

Before a case of association between characters in the hereditary process can be assigned to the category of linkage, it must be shown (1) that each character, followed separately, shows normal segregation in the Mendelian sense, and (2) that the relative distribution of the characters in a given generation differs in orderly fashion according as their gametic representatives entered the parental zygote together or apart. Only when these conditions are observed are we entitled to speak of a case as exhibiting the phenomenon of linkage.

Here it seems to me that Prof. MacBride becomes definitely misleading. In his letter of March 6, p. 340, he cites as a case of linkage the effects produced in the developing vertebrate embryo by alterations in amniotic pressure. No doubt such alterations produce simultaneous and definite effects in various organs. Such a statement, coming from such an authority on matters embryological, I do not dream of questioning. But when Prof MacBride cites this as an example of linkage, I assert that he has no right to do so until he, or some one else, has proved that it fulfils the conditions necessary to bring it under the heading of this phenomenon. Until this has been done, the case, interesting as it may be in other connexions, is here worthless. For it is quite likely that it has nothing whatever to do with linkage.

Mr. Tate Regan, too (NATURE, Jan. 16, p. 86), has fallen into the same error when, in flat fishes, he describes ambicoloration, monomorphic scales, and delayed migration of the eye as a linkage group. That these variations tend to occur together is well recognised, but here again we know nothing of their hereditary behaviour; and until we have some knowledge of this it is beside the mark to bring them forward. As Prof. Huxley suggests in his letter of February 20, p. 268, they may quite well be all dependent upon the operation of the same genetical factor. In the white sweet pea the colourless flower is always associated with a green axil and a pale brown seed coat, and these three associated characters can all be referred to the absence of one of the ingredients necessary to the production of anthocyan pigment. These associated characters, as experimental evidence has clearly shown, do *not* constitute a linkage group, and I suspect that this is more likely than not to be true also of Mr. Tate Regan's example. Further, in view of Mr. Tate Regan's later note of March 6, p. 341, I would add that the simultaneous appearance of mutations is, in so far as we know, quite unconnected with linkage. That such simultaneous mutations may show linkage is of course possible, but in all probability it is more likely that they will not.

In conclusion, I would lay further stress upon what Prof. Huxley has already clearly pointed out, namely, that the recognition of the orderly series of phenomena to which the term linkage has been applied does not necessarily entail acceptance of the chromosomal theory of heredity. That this theory at present offers the most plausible interpretation of linkage is admitted by the great majority of those who are best qualified to judge. Yet if the chromosomal theory were to be swept away to-morrow, the precise and clear-cut phenomenon of linkage would remain untouched.

R. C. PUNNETT.

Whittingehame Lodge, Cambridge.

The So-called Dielectric Constant.

IN NATURE of March 6, p. 361, an abstract of an address by Prof. Compton, entitled "Dielectric Constant and Molecular Structure," is given.

So early as 1889 it was known that dielectrics conduct electricity (see Curie, *Annales de Chimie et de Physique*, 1889), and that the so-called constant depends upon the time of charging, and when measured by the alternating method, upon the frequency (J. J. Thomson, *Roy. Soc. Proc.*, 1889).

I have shown (*Roy. Soc. Proc.*, 1915 and 1925) that when a potential v is applied to one surface of a condenser, the other surface being connected to the earth, the relation between the charging, polarising, and conduction currents is represented by

$$\gamma = \frac{dQ}{dT} + \frac{v - P}{R} \quad . \quad . \quad . \quad . \quad (1)$$

where γ = the charging current,

$\frac{dQ}{dT}$ = the polarising current (*i.e.*, the rate at which the charge is accumulating in the dielectric),

P = the electromotive force of polarisation of the dielectric,

and R = the true electrical resistance of the dielectric in the given circumstances.

After the current has been flowing for some time, $\frac{dQ}{dT}$ becomes negligible and the equation reduces to

$$\gamma = \frac{v - P}{R} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

For the discharge the equation reduces to

$$-\frac{dQ}{Td} = -\frac{P}{R} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Röntgen and Joffé (*Annalen der Physik*, vol. 72, 1923) have experimented on numerous substances (including pure crystals) in widely varying circumstances as to voltage and temperature, and their results confirm both (2) and (3).

I, myself, having performed many experiments (at constant temperature) on quartz along and across the optical axis, fused quartz, Iceland spar, rocksalt, glass, paraffin, ebonite, and xylol, have come to the conclusion that if one surface of a condenser be connected to the earth and the other surface be maintained at a potential v for a time T, the total charge accumulated in the condenser can be represented by

$$(K + K'_\tau)Cv,$$

where C = a constant depending on the size and arrangement of the conducting surfaces,

K = the specific inductive *instantaneous* capacity of the dielectric,

K'_τ = the *maximum* value of the specific inductive *residual* capacity,

and τ = the time taken for the potential of the surface originally at potential v (when connected to the earth) to fall to zero.

At any subsequent time, t (greater than τ), the charge remaining in the condenser, can be represented by

$$K_t'Cv,$$

where $$K'_t = nK_\tau' e^{x - a(t-\tau)}$$

and n = a constant for the given *specimen* of dielectric,

a = a function of T (the time of charging),

x = a function of both T and t.

When the discharge has taken place for some time this expression reduces to

$$K'_t = nK_\tau' e^{-at}.$$

The general behaviour of dielectrics is, however, at present little understood and cannot, I think, be represented adequately by any kind of simple model.

S. W. RICHARDSON.

Davy-Faraday Laboratory,
The Royal Institution,
21 Albemarle Street, W.1.

The Relation of Weight to Height during Adolescence.

AMONG the well-known anthropometric formulæ due to Prof. Dreyer of Oxford (see *Lancet*, August 9, 1919, and NATURE, August 26, 1920), there is one connecting weight, W, with stem-length, or height of trunk alone, λ, namely, $W = 0{\cdot}380\sqrt[0{\cdot}319]{\lambda}$. This gives a ratio of the type $W^n/\lambda = K$, and is of special interest because, when dealing with averages of large numbers, it seems to show surprisingly little variation with age during the important adolescent period of life. To test it I used data relating to Manchester Grammar School boys, for which I am indebted to Dr. Mumford, Medical Officer of the School. The school measurements of height and weight have been taken on a uniform basis for about forty years; measurements of stem-length were taken in addition in 1921 and 1923. If the stem-length is replaced by the full height (H), and if 0·319 (n) is replaced by the approximate value ⅓ in Dreyer's formula, I find that the ratio is even less variable. Table 1 shows the values of $W^{\frac{1}{3}}/H$, calculated from the mean values of W and H, for groups of boys varying in age from 9 to 19 years at three different periods of time. In the same table are shown, for comparison, calculations of the same ratio for Schuster's observations of undergraduates, and of $W^{0\cdot 319}/\lambda$ for the Grammar School boys in 1921, 1923. Measurements were expressed in C.G.S. units, but significant figures only are printed.

In order to get a more precise measure of the variability, the standard deviations of the 1921, 1923 values of $W^{\frac{1}{3}}/H$ and $W^{0\cdot 319}/\lambda$ at different ages were also determined, being measured from the weighted means of all the observations in each case. To render them comparable, these standard deviations were expressed as percentages of the corresponding weighted means; the resulting coefficient of variation for $W^{0\cdot 319}/\lambda$ was 0·66 per cent and for $W^{\frac{1}{3}}/H$ was 0·37 per cent. This is a further corroboration of the conclusion to which Mumford and Young came (*Biometrika*, August 1923): "Despite the definite tendency shown in recent work on the inter-relationships of the physical measurements to replace the full-length by the stem-length, the latter does not possess the many advantages over the former that have been frequently claimed or asserted. It would almost appear to be a matter of indifference as to which measurement of length is used"

TABLE 1.

Variability of $W^{\frac{1}{3}}/H$ and $W^{0\cdot 319}/\lambda$ at Different Periods and Ages.

TABLE 2.

ELEMENTARY SCHOOL-BOYS IN LIVERPOOL (1923).

Comparison of Values of $W^{\frac{1}{3}}/H$ at Different Ages according to Class of District.

Age.	Class of District. (Number of Observations.)			Class of District. ($W^{\frac{1}{3}}/H$).		
	Poor.	Fair.	Good.	Poor.	Fair.	Good.
5½	222	363	236	254	249	245
6½	147	195	209	249	246	242
8½	413	539	412	242	240	234
12½	420	461	317	234	232	235
13½	175	124	94	233	232	230

It may be stated that the ratio $W^{\frac{1}{3}}/H$ was also worked out individually for a random sample of 50 boys in the same school in the summer of 1924. The boys varied in age from 13 to 19 years. There were two exceptional boys in the group for whom the ratio was so high as 244 and 260 respectively; for the rest, it varied between the limits 216 and 238. For the whole group the lower and upper quartiles were 224 and 233; the arithmetic mean was 229; the standard deviation, 74·7; and the coefficient of variation, 3·3 per cent.

The formula $W^{\frac{1}{3}}/H = K$ is a well-established one. Quetelet himself said that the weight of the human body, if it were symmetrical, would vary as the cube of the height, though his observations led him to the opinion that "in general, we do not err much when we assume that, during development, the squares of the weight at different ages are as the fifth powers of the heights." Hutchinson, later, decided that W varied as the 2·75th power of H. Livi had introduced the ratio $W^{\frac{1}{3}}/H$ into general and comparative anthropometry under the name "ponderal index," and it has been used on the Continent for many years as an index of nutrition among school children.

Table 2 may be of interest as bearing on the nutrition question. It analyses the values of $W^{\frac{1}{3}}/H$, calculated upon the mean values of W and H, for elementary school-boys in Liverpool, at different ages from 5 to 14 years, according to the class of district where each school is located. (Data from the Report of the Medical Officer, Liverpool, 1923.) Note that the index during these early years falls as the age increases and, if we may assume that the boys from the better districts are the better nourished, the index also falls as the nutrition increases. To this there is only one exception, namely, in the 'good' district at age 12½ years.

It is doubtful, however, whether the claim to treat $W^{\frac{1}{3}}/H$ as a trustworthy index of nutrition has ever been properly established. Other factors certainly affect the index besides nutrition, for example, muscular activity, hours of sleep, and home conditions generally; exercise under healthy conditions promotes growth in height and weight, but absolute rest with a nourishing diet likewise promotes growth; some illnesses seem to have a stimulating effect on the growth of the skeleton, perhaps by removing the muscular tension which acts on bone. But apart from its possible value as a nutrition index, more especially in dealing with children somewhere near the poverty line, the ratio $W^{\frac{1}{3}}/H$ might serve a useful purpose as the basis of a table, like the Dreyer tables, connecting weight, stem-length, vital capacity, and chest girth, providing a gauge of the approximate weight to be expected in a normal boy of given height and given class.

References and Re-paging of Reprints.

AGAINST the re-paging of reprints, the British Association Committee on Zoological Bibliography and Publication has protested since its foundation in 1895, and it has always taken the view that this and similar matters are in the control of editors, to whom accordingly its recommendations have been addressed. It is therefore refreshing at last to find an editor, in the person of Dr. Rastall, associating himself so whole-heartedly with the protest (NATURE, March 20, 1926, p. 418). *Experientia docet.*

In the same number of NATURE (p. 425), in allusion to the work of the Bureau of Chemical Abstracts in "endeavouring to secure uniformity in the method of referring to original papers," you justly say that "on questions common to all sciences the views of other bodies . . . must be considered." Here again the above-mentioned British Association Committee has for many years past urged the general adoption of a method already widely in use among biologists, especially in the United States. Here the order is:

author, date, title, journal, series, volume, page. The committee advocates giving the year number in full, since zoology at any rate neither began nor ended with the nineteenth century. If this be done and a logical order followed, both 1825, 10, 6, and 6, 10, 1825 are equally intelligible, though personally I prefer 'Oct.' to '10' or 'X.' The intercalation of the date between volume and page-numbers is illogical and often misleading.

F. A. BATHER,

March 20.

I THOUGHT that this pernicious custom had long ago disappeared for ever. Any one who has occasion to refer to the long series of papers on the Nomenclature of the Foraminifera in the *Am. Mag. Nat. Hist.*, 1859–72, will cordially endorse Dr. Rastall (NATURE, March 20, p. 418). References to these in synonymies are made indifferently to the journal and its reprints, and it is never safe to rely upon them.

There exists, however, a far more ghastly crime than the mere re-pagination of reprints. One looks with suspicion on a page reference (say 1-20), but one is tempted to accept as 'original' page references (say) 100 *et seq.* But the late Charles Schlumberger used to have his reprints paged consecutively—*and left out his own pagination when he was not allowed to do so*, and took it up again when he was. The awful result was as follows. His first paper was re-paged 1-3; his second was not re-paged, and he allowed for this in his third, which was re-paged 10-19 with a second part paged 20-23, *and he allowed for his new title wrappers*, so his next was re-paged 27-34, the next 35-37, the next 39-89, and so it went on until 1894, when he had reached pp. 237-243, an unre-paged reprint, which had its original pagination 118-123, coming between pp. 222 and 237. After this, probably yielding to infuriated pressure, he abandoned the system, but the mischief was done, and no page reference to any of his twenty-one papers (up to 1894) is to be accepted without reference to the original journal.

It would be interesting to know whether any other writer ever committed this outrage upon posterity

EDWARD HERON-ALLEN.

The Evolution of Rosa.

THE recently published paper of Dr. C. C. Hurst ("Experiments in Genetics," 38, 1925) on the chromosomes and characters in Rosa may well mark a new epoch in biology. We must await the appearance of his monograph for full details, but as he suggests, we may in the meanwhile try to apply the 'Rosa principles' to other plants and animals. It is suggested that the common ancestor of all roses was a northern decaploid species, at present unknown. The various forms could have arisen by the dropping out of sets of chromosomes, the existing five diploid types being the end-products of this process. We are told, however, that "certain cultivated triploid and tetraploid forms are obviously duplicated forms which have arisen . . . by duplication of the septets of chromosomes." These maintain the essential specific characters of the original diploid species, instead of showing a complex of the characters of diverse septets. Is it not possible to suppose that this duplication may have been the first step in the production of polyploid species, the latter acquiring the diverse septet characters by successive mutations? The Drosophila work has shown that mutations are likely to be lethal or unfavourable. In a diploid species such mutations should apparently work more havoc than in a polyploid one. Polyploidy might then be a condition favouring the survival and accumulation of mutated genes, resulting after very long periods of time in diversity of the septets. Such diversity might come to have its advantages, as Dr. Hurst indicates, in specific cases. On the other hand, in some cases the shedding of a septet might be advantageous, getting rid of some undesirable features, and producing a more uniform or consistent type. Thus the diploid *R. rugosa*, which I found to be a strictly sea-coast plant in Siberia, is a well-defined type specially adapted to its peculiar habitats but not extending even a few miles inland. Yet it is not to be expected that the diploids will all be successful, and close field study combined with cytological research may be expected to reveal a variety of forms with reduced chromosome numbers, coming into existence only to perish at once or in a few years. Many, probably, may not even be capable of development.

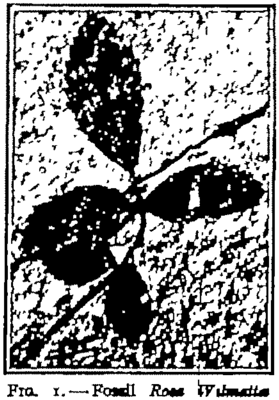

FIG. 1.—Fossil *Rosa Wilmattae* Cockerell, from the Miocene of Florissant, Colorado.

Possibly, then, there is a double process going on, and it may not appear certain that the original rose was decaploid, though the existing diploids may all be derived from polyploid ancestors. There has been time for much to happen, for we know from the Miocene of Florissant several species of roses extraordinarily like those of the present day (cf. Fig. 1).

The Banana in America.

As a student of culture-history I must protest against the inferences drawn by Dr. E. W. Berry from the finding of fossil banana seeds in Tertiary beds in Colombia which were referred to in NATURE, February 6, 1926, p. 209.

The moot-problem resolves itself into two questions. What is the value of the early references to the banana as a plant cultivated by the natives prior to the possible introduction of the cultivated banana? And, what follows from the indigenousness of the wild banana as to its cultivation by the aborigines? The 'historical evidence' for the pre-Colombian cultivation of the banana is considered quite unconvincing by such authorities as Baron Erland Nordenskiold, who writes: "It may be regarded as proved by De Candolle and Karl v. d. Steinen that the banana was introduced into America by the whites" ("Comparative Ethnographical Studies," vol. 5, 1922, 64 *sq.*). On the other hand, the conclusion that *if* the banana was indigenous in America it must have been cultivated by the natives is a monstrous *non sequitur* that might be labelled a typical 'botanist's fallacy,' were the sobriquet not unjust to many botanists keenly alive to the historical questions involved in the history of cultivation. This methodological question has been so adequately treated in Dr. B. Laufer's "Sino-Iranica" (Chicago, 1919), that I will here content myself with a reference to that treasure-trove of information. It no more follows that, say, the Peruvians would cultivate a wild plant found in their territory than that the Eskimo would domesticate the caribou. As Laufer has shown, the Chinese had the wild walnut and a wild vine, but it never occurred to them to cultivate either.

Though the botanical aspects of the question are beyond the sphere of my competence, I should like to refer the reader to E. Werth's paper on the banana ("Zur Natur- und Kulturgeschichte der Banana,"–in *Festschrift Eduard Hahn*, 1917, 22-50). The author shows—satisfactorily, so far as a layman can judge—that the African wild species, *Musa ensete*, could not by any possibility have given rise to the cultivated banana. So far as I remember the report of Dr. Berry's paper in *Science*, his Colombian banana is of the African type and must accordingly be ruled out as a possible ancestor of the cultivated forms.

Phyllody in the Primrose Flower.

Through the medium of the columns of Nature, may I record the occurrence in this neighbourhood of a pair of plants of *Primula Vulgaris* (Huds.), both of which illustrate the phenomenon of phyllody of the sepals.

The calyx is the whorl of floral leaves chiefly involved. The teeth of the calyx, normally narrow and sharply pointed, have become revolute, acuminate, miniature leaves above the tubular portion, while this latter part has—but for slight increase in size—retained the normal tubular form, the veins being rather more obvious. Tracing this increase in foliar characters in the sepals through several flowers, it was noticed that the increase is accompanied by a decrease in the size of the individuals of the corolla.

The stamens (the flowers in every case in both plants were 'thrum-eyed') and pistil were in all cases normal in appearance, but the more the reversion characters were developed in individual flowers the shorter was their duration. Normal flowers on normal plants are still flowering while the diminutive corollas and staminate parts of the retrogressive flowers withered within four days of opening.

The measurements of the foliar sepals are: 1·45 cm. from top of calyx tube to acuminate point; 1·20 cm. broad at the greatest breadth. These figures represent the average for the five sepals of the flower exhibiting the greatest reversion. The average diameter of the most abnormal flower is 3·2 cm., measuring across the sepal expansion.

The plants are being maintained in the laboratory here, and will be watched through subsequent seasons. The seeds of the abnormal flowers will be sown.

The Crystalline Style and Anaerobic Respiration.

The review of the *Journal of the Marine Biological Association* (vol. 13, No. 4) in Nature of January 2, p. 31, has directed my attention to the very interesting paper by Dr. Yonge on the hydrogen ion concentration in the gut of certain lamellibranchs and gastropods. In the course of this paper Dr. Yonge criticises my suggestion (*J. of Exp. Zool.*, vol. 37, p. 477) that the disappearance of the crystalline style from certain marine molluscs when they are kept under anaerobic conditions may be, in part, a direct response to the lack of oxygen. Dr. Yonge holds that the disappearance of the style is "probably due to a lowering of the vital activities" of the animals, amongst which the secretion of the style-forming material is one, and that in the case of an animal the vital activity of which is thus reduced, the secretion cannot keep pace with the consumption of the style substance for digestive purposes. The style consequently disappears.

The evidence which Dr. Yonge and others have brought forward seems to leave it beyond doubt that the crystalline style plays an important part in digestion, but this does not exclude the possibility that it may also be connected with, and affected by, anaerobic respiration. Dr. Yonge's experiments do not seem to have been designed to differentiate the two possible functions, since the only methods employed by him to lower the vital activity of the animals with which he worked involved keeping them under anaerobic conditions. May not the resulting dissolution of the style be an expression of an effort on the part of the animal to offset the strain on its vital activity induced by anaerobiosis as well as by the necessity to maintain the acid condition of the gut for the purpose of digestion? The facts that the style disappears under anaerobic conditions and is regenerated by aeration *in the total absence of food material to digest* seems rather to point in that direction.

It seems to me that the matter must be considered *sub judice* until a series of experiments can be designed to follow the possibly manifold functions of the style independently of one another.

Renewed Activity of Cameroon Mountain.

Cameroon Mountain, which has been more or less dormant since the last eruption in 1922, has recently been showing signs of renewed activity The following extract from a letter by Mr. E. J. Arnett, Senior Resident, Cameroons Province, dated November 30, 1925, may be of interest to readers of Nature:

"You may be interested to know that the summit of the mountain is showing more signs of activity than for some time past. There is a large old crater on the west side of the summit about 400 yards in diameter and 150 feet deep. From its western and southern lip the ground falls rapidly away, and this face of it is visible from the 12,000-foot ridge as the mountain is ascended from Buea. This south-west face was seen to be white with fresh ash and steaming when I ascended the mountain on 29th instant accompanied by Mr. J. C. Drummond-Hay and Mr. C. W. Seed, Auditor.

"On reaching the top we found the whole circumference of this crater was white and steaming and the ground hot to the tread for some way back, with many small fissures giving out steam. The bottom of the crater was evidently cold, as the lichen-covered rocks which appeared to have fallen from the lip were fresh and green.

"Beyond the summit, *i.e.* north-west of it, between it and an almost equally high peak, there is a long valley or crater in which are a number of recently formed circular pits varying in diameter from 3 to 20 feet. These, it appears, have been formed during the past three months, but are now quite cold and black. There are about a dozen of these holes in a rough line running south-east and north-west."

Diatoms and Flocculent Matter.

In old microscopical journals, one frequently finds the query "How can I get rid of flocculent matter in preparing diatoms for mounting?" and as a rule there is no answer to the question.

The desired result can be attained by pouring the water containing the cleared diatoms into a glass bowl and letting it stand until the diatoms have settled and all eddies have died out in the liquid. By inclining the bowl sideways and giving it a gentle rocking motion a quantity of flocculent matter will be detached and can easily be made to roll up into small lumps and drawn away from the diatoms, when the lumps can be sucked up with a glass syringe. The process can be repeated over and over again till nothing but pure diatoms are left. The necessary rolling action is caused by viscosity, and except at the surface of the bowl the small oscillations of the fluid are practically irrotational. The diatoms mostly collect at the edge of the receding liquid, but it is important that the operation should be performed in the shade, as otherwise "greasiness" is produced by the evolution of air, and the diatoms float and stick on the surface of the water.

When all the flocculent matter is removed the fluid is stirred up by the syringe and then sucked up and deposited on the cover-glass, when the diatoms will be found to be perfectly evenly distributed, and the cover-glass must be left untouched and protected from dust until the water has dried. It is almost impossible to avoid impurities being deposited round the edge of the cover-glass, and it is my practice to wipe off a narrow margin, the central part being clean. The method of cleaning answers equally well for the desmids found in the sphagnum pools in North Wales.

I have collected diatoms from very unpromising localities by washing a quantity of seaweed in a large basin and emptying the basin by suddenly reversing it and immediately restoring it. The tiny pool of water left in the basin is usually full of diatoms, and if slowly drained off sand will be left behind.

American Official Publications.

I beg leave to direct attention to the lack of facility for obtaining the official scientific publications of the various departments of the United States Government. If it is desired to obtain a copy of one of these, it is necessary to write to Washington, enclosing the anticipated and approximate sum for payment, and in due course the publication arrives. Such a procedure necessitates a delay of about a fortnight at the very least, and the accredited agents of the U.S.A. Government in this country inform me that more than a month may elapse before the information is received.

It is obvious that such delay is annoying and undesirable, the more so because many of these publications are of real value for the careful work they contain. Consultation at a library is not always satisfactory, as the various series may not be complete and are not invariably in a condition suitable for quick reference: in any case, personal possession is usually more satisfactory and is often imperative.

Some time ago I brought this matter before my friend Dr. George M'Lean, who was on a visit from the United States in order to report to his government on the British universities, and afterwards became so valuable as a link between American students and British and French centres of learning. I do not know whether or not he took any action, but, so far as I am aware, the situation remains the same as it always has been.

It would, I consider, be of considerable value for arrangements to be made so that all the U.S.A. official publications could be purchased in Great Britain as soon as they can arrive here after their issue in America. There can be no doubt as to the practical and educational value of such an arrangement, which might include a somewhat widespread distribution, at a nominal fee, of periodic lists of the various Bureaux and Departments.

The Use of an Artificial Horizon in Photographic Measurements of Buildings or other Structures.

In a letter in Nature for March 6, p. 338, Mr. Mallock records his method of using an artificial horizon in photographic measurements of buildings. The method, as described, would of course give a permanent and easily studied record, but it appears to the present writer as needlessly complex. No mention is made by Mr. Mallock of a modern phototheodolite which, set up and in adjustment, would give, without the need for an artificial horizon, all the information required. The setting up, usually by means of an attached bubble, introduces into the instrument the desired vertical. The correlation of this vertical with the image on the photographic plate is a practical matter of 'check' or 'adjustment' on the instrument itself. This 'setting up' or levelling of the camera is essential in the case of any photographic recording instrument for such a purpose. Having thus obtained a true vertical, it appears unnecessary again to secure it by means of an artificial horizon. The method of indicating fundamental directions on the plate would be a matter of choice. It might be a series of fiducial vertical lines or simple marks in the photograph to indicate vertical and horizontal planes. Unless the artificial horizon has merits not fully appreciated by me, it would appear better to carry out such work with a simpler and practically standard equipment.

Mr. Mallock's very interesting letter does, however, suggest the question as to whether periodic photo surveys of our more important public buildings might not be part of upkeep routine. The survey need not be expensive and the records could be studied at leisure. Photographic surveys at ten-yearly periods, or as required, would be a safeguard against unsuspected subsidence or other changes.

Did Davy melt Ice by Friction in a Vacuum?

Quite firmly entrenched in scientific literature, including some very recent English histories of science, is the statement that Sir Humphry Davy contrived a clockwork by which two pieces of ice were rubbed together and made to melt under the exhausted receiver of an air-pump. This is incorrect. A reference to Davy's works (Davy, "Collected Works," vol 2, 1839, p. 11, 12, "Experiment II." and "Experiment III.") indicates that in one experiment he melted ice at 29° F., by friction, *in the open*, and that in another experiment he caused *wax* to melt by friction of two metals (wheel and plate) *in a vacuum*. Davy did not melt ice by rubbing together pieces of ice in a vacuum.

University of California.

Tests of Relativity Theory.[1]

By Prof. A. S. EVE, C.B.E., F.R.S., McGill University, Montreal.

> *"They say miracles are past; and we have our philosophical persons, to make modern and familiar, things supernatural and causeless. Hence it is that we make trifles of terrors, ensconcing ourselves into seeming knowledge, when we should submit ourselves to an unknown fear."*—SHAKESPEARE ("All's Well that Ends Well").

THOSE who were fortunate enough to attend the meeting of the American Physical Society at Kansas City in January, found ample food for reflection on the strange but interesting position into which the experimental tests of the consequences of the theory of relativity have now passed.

This theory, first received with reluctance, is now held with extreme tenacity. In some form or other, it has come to stay. It can be modified, but not annihilated. It may, indeed, fall into line with evolution which every one believes, few can define, and no one can "explain." Its disproof has become a far more formidable task than its proof.

Those, however, who carry relativistic ideas beyond their proper sphere of mathematical physics will do well to ponder the intensive limerick of Father Ronald Knox—

"There was a young man who said God
Must think it excessively odd
That the sycamore tree
Just ceases to be
When there's no one about in the Quad."

But surely we are wandering from Kansas!

What then are the experimental tests to which the theory or theories of relativity may be subjected? Mainly five:

(1) The gradual shift of the perihelion of Mercury stated to be 41″ per century and found by Einstein to be 43″. Here, as elsewhere, no sooner is the calculated found to agree with the observed value, than the latter becomes elusive and fresh calculation gives widely differing numbers, 38″ or even 29″, so that Einstein has to build not on a rock but on a quicksand.

(2) The bending of the rays of light passing near the sun's surface, verifiable only at time of total eclipse. This story is too well known to be retold. British and also, especially, American astronomers are well satisfied that the verification is amply complete; but there are many astronomers and physicists who are well aware that this verified effect may be assigned to a number of other causes, particularly to refraction.

(3) At Kansas City, Dr. St. John gave a most complete account of his exhaustive inquiry into the shift towards the red in the spectrum of the sun, a shift to which Einstein attached so much importance that he is reported to have said that if the shift did not exist, then his theory of relativity was wrong. This statement is not upheld by Silberstein, who in his exquisite treatise on "The Theory of Relativity" (p. 392) points out that the period of an atom on the sun need not necessarily be the same as the corresponding period of a similar atom on the earth, as is commonly assumed. The full relation is

$$\lambda_{\text{sun}}/\lambda_{\text{earth}} = \left(1 + \frac{M}{c^2R}\right)\tau_{\text{sun}}/\tau_{\text{earth}},$$

where λ is the wave-length corresponding to period τ ($\lambda = c\tau$, of course), M is the mass, R the radius of the sun, and c as usual the velocity of light. Einstein assumes $\tau_{\text{sun}} = \tau_{\text{earth}}$ (but it need not be so),[2] and in that case $\lambda_{\text{sun}}/\lambda_{\text{earth}} = 1 + \frac{1{\cdot}75}{8 \times 10^5}$, so that $d\lambda/\lambda = 2{\cdot}11 \times 10^{-6}$, amounting to 0·008 of an Ångström unit in the blue.

This shift is certified by St. John and by Evershed to be true for the sun. Incidentally the testing of this relation has stimulated an enormous amount of research into the character and motion of the sun's atmosphere. In addition to the horizontal motions due to the sun's rotation and other causes, there are vertical motions varying with elevation, each producing its baffling Doppler effect overlapping the Einstein shift. Strangely enough, the pressure shift can be ignored, for it is estimated, even at the very base near the photosphere, that the pressure of this flaming atmosphere fourteen thousand kilometres thick is but one-tenth of our atmosphere!

Where calcium is first ionised the pressure is but one ten-thousandth, and passing upwards through the regions of the sodium D lines on to the H_α and H_β, we arrive near the top to a pressure of 10^{-13} earth's atmosphere where Ca^+ exists, and the calcium atom enjoys the privilege of losing a second electron.

The full evidence, standing by itself, would testify as much to the skill of the astronomers as to the accuracy of the theory, without any reflection on their transcendent honesty of purpose.

But the real treat of the meeting was yet to come. St. John threw on the screen a photograph of the spectra of Sirius and of its illustrious companion, the White Dwarf. The consequent applause of a large audience told its own tale. The spectrum of the companion was bordered on each side by the scattered light of Sirius. On the right at the red end the companion's spectrum was conspicuously clear; at the other end the blue of Sirius largely overwhelmed it. The predicted shift in this case is 34 times that in the sun, amounting to 21 km./sec., while the measured shift gave for H_β, 26 km./sec.; for H_γ, 21 km./sec.; for other lines, 22 km./sec.—mean, 23 km./sec. Here was indeed an unmistakable and emphatic triumph for Einstein of undoubted and overwhelming importance. Shall we not also pay a tribute to the genius of Eddington, who foresaw the possibility of a gaseous star of atoms completely stripped, and therefore giving rise to little radiation pressure, resulting in a compactness hitherto unconceived, amounting to a density fifty thousand times that of water?

---

[1] From a lecture given to the Physical Society of McGill University, Montreal, January 1926.

[2] This is the answer to Sir Oliver Lodge's recent letter to NATURE (December 26, 1925, p. 938).

(4) At a joint meeting with the American Association for the Advancement of Science (a close relative of the British Association in type and design), the American Physical Society had the pleasure at Kansas of hearing their illustrious president, D. C. Miller, give a clear and interesting account of his latest results on the famous Michelson-Morley-Miller experiment as carried out by him on Mount Wilson. He has, in 1925, carried out a long series of continuous experiments which exceed in quantity and weight all previous experiments of this type He has taken every precaution of which the most careful of physicists is capable; he has listened and given heed to the suggestions of critical friends, for he is a man without enemies. He has kept aloof from preconceptions and refused to be dragged into controversy. *He proclaims definitely a positive result indicating an earth motion through space of 10 km./sec.* The direction of motion is 6° from the south pole of the solar system, as if our system was like a falling leaf moving broadside on to its proper motion. It will be recollected that in 1887 Michelson and Morley obtained a displacement of 0·02 of an interference fringe, whereas the stagnant ether theory indicated that $2v^2L/c^2\lambda$ should give 0·4 of the said fringe. This was *assumed* to be a null effect.

In 1905 Morley and Miller at Cleveland obtained 0·0075 out of 1·5. Then followed the Rayleigh and Bruce double refraction experiment, the Trouton and Noble capacity experiment, the Fitzgerald and Lorentz shortening theory, and ultimately the special and generalised theories of relativity of Einstein.

Now, mixing metaphors, we see the very experiment, which first started the ball a-rolling, turning round to bite the hand which fed it. Yet we seek intuitively, and therefore possibly wrongfully, for some explanation of Miller's result other than the abandonment of the theory of relativity. Why? Because other experiments are in favour of it? Partly, no doubt. Chiefly, I think, because the space contraction and time elongation of Einstein make the Maxwell equations transformable, and because the change of mass with speed, well verified for β-rays, agree with a rational outlook on a universe where we find only electrical phenomena exhibited as energy in a metrical space-time. Minkowski's work is as persuasive as a great experiment. But the matter will not rest here, for already American physicists are contemplating more experiments at different levels and localities. Rumour has it that Millikan has in hand a portable apparatus. Critics have pointed out that 10 km./sec. a second on Mount Wilson and zero at sea-level would perturb the agreement of astronomical data from various observatories. But Miller has never suggested zero at sea-level, and observatories do have 'personal equations' no less than individual observers. The situation is one requiring patience and experiment rather than speculation at present.

Miller has, however, taken a further step which is quite independent of the positive result of 10 km./sec. above stated, and no less of his deduced direction of motion. He finds that he can get a satisfactory explanation of all his results if he assumes that the solar system is moving with a velocity of 200 kilometres a second (*or more, not less*), relative to the ether. If that is so, then the earth must *drag* 95 per cent. of the ether with it and 5 per cent. must *slip* past the earth. Here we have a revival of the ideas of Stokes, with possibly Planck's addition of immense compressibility due possibly to gravitation. To the writer this idea suggests profound difficulty. For example, the ether would have a vastly larger condensation round the sun than round the earth. However that may be, it appears true that if Miller's results are confirmed at different places, then all our theories go into the melting-pot, relativity and all, and a patient resurvey must commence to unravel afresh order from chaos. The only grave mistake which we can make at present is to treat Miller's main results otherwise than seriously.

(5) It is a relief to pass from the profound difficulties of the second-order experiments to the conspicuous success of the great first-order effect devised by Michelson, advocated strenuously by Silberstein, and carried out so efficiently by Gale and his co-workers. The results of the famous Chicago rotation experiment are equally explainable by the old view of a stagnant ether, or by the Einstein relativity theory. It is no less opposed to the Stokes drag theory, or to Miller's suggestion of 10 km./sec. slip and 190, or more, km./sec. drag. The compromise of Silberstein that in rotation there is full drag, and that in translation there is a partial drag, will suit the experimental evidence in hand, but no one seriously supposes that such will be the ultimate result of further experiments.

At the meeting at Kansas, in the unavoidable absence of Gale, a graphic account of the Chicago experiment was given by Watson, who was himself engaged in the work. His description dealt with the body rather than the soul of it.

If two runners start back to back and run with equal speeds in opposite directions round a circular track, they will pass each other again at the starting-point. If one runs faster than the other, there will be a difference. So if light is sent round in opposite ways a many-sided polygon approximating to a circle of radius r, say at the north pole, there will be a time difference

$$\frac{2\pi r}{c-v}-\frac{2\pi r}{c+v} \text{ or } \frac{4\pi r v}{c^2},$$

and this becomes

$$\frac{4\pi r^2\omega}{c^2},$$

or

$$\text{the area} \times 4\omega/c^2;$$

where r is the radius of the track; v, or ωr, the velocity due to earth's rotation. This circulation of light in opposite ways still depends upon the *area*, whatever the shape of the track round which the divided beams circulate. In latitude l there is a factor $\sin l$ to be introduced, and there results a lag in wave-length of $4 \times \text{area} \times \omega \sin l/c^2\lambda$, with an observed value 0·230, as against a calculated value of 0·236, or a verification within three per cent. In place of the crude proof above, there is the relativity proof in Silberstein's "Theory of Relativity" (p. 382), and other proofs may readily be derived, for it is hard to arrive at any other result by any first-order principle. The result of the experiment is equally gratifying to the relativist and to the classicist. It was pointed out to the writer by K. T. Compton that this uncertainty of 3 per cent. might cover the failure to detect the 5 per cent. slip (20 out of 200 km./sec. or more) which Miller's result might suggest.

As Watson described this heroic experiment, a feeling of disappointment arose that such glorious apparatus had to be dismantled. The pipes (14 in.) were well and truly laid over a large area, and it was necessary to make good joints to get a vacuum, but winter was coming on and frost would have displaced the pipes, so that it is a greater matter for congratulation that this fine experiment should have been carried out, than that the apparatus should have been dismantled and removed.

It is possible to summarise the situation:

For Relativity.	*Against Relativity, but for drag and slip.*
Mercury perihelion (?). Eclipse results. Spectrum shift.	Miller's experiments on Mount Wilson.
For Relativity or for Stagnant Ether, but against drag and slip. Michelson-Gale-Silberstein. Chicago rotation experiment.	

This brief and imperfect record of a difficult subject is written for those who are interested in the situation as it appeared to one who attended the meetings at Kansas City.

Some Properties of the Vitamins.

THE reality of the existence of the three well-known vitamins having been confirmed by numerous careful investigations, attention was directed to their isolation in a pure state, with the ultimate aim of discovering their chemical constitution. At first the work was largely qualitative, but with improvement in the technique of the necessary animal experiments, quantitative investigations became possible, and have led not only to a great increase in our knowledge of these elusive substances, but also to the probable discovery of further members of the series. Whilst undue multiplication of the number of unknown accessory food factors must be deprecated, yet it must be admitted that recent work suggests that there exist besides the orthodox trinity, an antirachitic factor D and an antisterility vitamin E: at the same time, our knowledge of their chemical properties has advanced so considerably, especially in the case of the fat-soluble vitamins A and D, that some of them may soon be justifiably transferred to a place amongst compounds of a similar chemical constitution. Thus the multiplication of vitamins resolves itself into the problem of the identification of substances which are required in metabolism only in minute amounts, and the discovery of which has been delayed until recently owing to difficulties of chemical analysis, and to the fact that they are usually present in the natural food of animals in adequate amount. Similar problems can be found in other branches of biochemistry and metabolism: thus all the amino-acids which make up the protein molecule have not yet probably been isolated, and vitamins are not the only substances which are required in minute quantities—for example, certain elements such as iodine.

Recent investigation has made it clear that the fat-soluble vitamins are present in the unsaponifiable portion of the fat, and that cholesterol can be removed from this fraction without impairing its efficacy. Takahashi and his co-workers have now carried our knowledge a stage further in an elaborate investigation (K. Takahashi, Z. Nakamiya, K. Kawakami, and T. Kitasato, *Scient. Papers, Inst. Phys. and Chem. Res., Tokyo,* 1925, vol. 3, p. 81). Starting with cod-liver oil or green leaves, the unsaponifiable fraction was obtained in a fairly pure condition and the cholesterol removed; some further purification of the product isolated from the former source was attempted by crystallisation from acetone at −60° to −70° C., followed by distillation at 147°-150° C. under 0·02-0·03 mm. pressure. These drastic treatments did not appear to destroy the vitamin, but did not effect any great purification: the products obtained from the two sources are somewhat different in composition, that from the oil being the more unsaturated. The yields of the crude material were of the order of 0·1 per cent of the oil and 0·025 per cent of the dried leaves. Tested on animals (rats), about 0·04 mgm. of the crude material or 0·005 mgm. of the purified product sufficed, when given daily to each animal, to promote growth on a diet deficient only in vitamin A.

The Japanese investigators have made a lengthy investigation into the physical and chemical properties of their refined product, which they have labelled 'Biosterin.' It has an absorption band in the ultra-violet, it is soluble in the organic solvents, but is unstable in ether and chloroform, and it is adsorbed by fuller's earth and animal charcoal. It also produces a photo-chemical action upon photographic plates, which the authors suggest, as the result of a series of experiments, is due to the formation of active oxygen from the oxygen of the air over the material: a similar effect was found to be produced, though less markedly, by the cod-liver oil itself, and also, but very feebly, by olive oil. As mentioned above, the vitamin is also stable to heat, in the absence of air. O. Rosenheim and J. C. Drummond (*Biochem. Journ.*, 1925, vol. 19, p. 753) have also shown that the cholesterol free unsaponifiable fraction of cod-liver oil containing the vitamin can be distilled in superheated steam in an atmosphere of nitrogen or in a high vacuum without loss of activity. On the other hand, H. W. Southgate (*ibid.*, p. 733) has found that when the cod-liver oil itself is heated to 200° C. in an atmosphere of carbon dioxide, and maintained at this temperature for varying lengths of time, a slow destruction of both the growth-promoting and the antirachitic factors takes place: the author was unable to show that this destruction was due to the liberation of fatty acids by hydrolysis at the high temperature used.

The stability to heat of these vitamins is of considerable practical importance: thus they are likely to be found in certain foods, such as milk, which has been dried by means of heat. Gladys A. Hartwell (*Brit. Med. Journ.*, 1925, vol. 1, p. 1073) has shown that both dried and evaporated milks form, together with white bread, diets adequate for growth and reproduction in rats: the former was as good as, or better than, fresh cow's milk, whilst the latter was distinctly inferior, this inferiority showing itself more especially when the animals reached adult size. It is possible that this difference is due to a relative deficiency of vitamin B in the evaporated milk. It must be pointed out that these results do not imply an adequate supply of vitamin C, since the rat requires extremely little of this vitamin compared to the guinea-pig or man: moreover, vitamin C is the most sensitive to the ordinary destructive agents. Katharine H. Coward (*Biochem. Journ.*, 1925, vol. 19, p. 500) has found also that drying green leaves need not destroy vitamin A, though it appears to vanish in leaves which are allowed to wither. The importance of the vitamin content of milk appears again in some recent experiments by H. Pringle (*Sci. Proc. Roy. Dub. Soc.*, 1925, vol. 18, p. 93). Human milk was found to be less efficient in promoting the growth of young rats than cow's milk, probably owing to a deficiency in vitamin B content. Thus again is the importance of the mother's diet during pregnancy and lactation emphasised.

Takahashi and his co-workers have carried out a number of analyses of the purified products obtained from cod-liver oil and green leaves, and suggest that their formulæ should be $C_{27}H_{44}O_2$ and $C_{27}H_{46}O_2$ respectively: for comparison, that of cholesterol, $C_{27}H_{46}O$, may also be given. A large series of chemical derivatives have been prepared, from which the authors have deduced that the oxygen atoms are present as OH groups, one a tertiary, and the other a primary or secondary alcohol, and that the products are unsaturated, containing three double bonds: they are also capable of reduction, and form a digitonide but less readily than cholesterol: on standing they slowly take up oxygen. In general, it may be stated that any change in the molecule results in a loss of the growth-promoting property. Cholesterol and its oxy derivative, which has the same formula as the product obtained from green leaves, are also inactive.

At the present time the most useful chemical property of vitamin A is probably that of producing a blue colour in the presence of certain reagents. Takahashi has investigated this side of the subject, using a number of different reagents, such as sulphuric acid and fuller's earth: inactive allied products give a reddish colour under similar conditions. Rosenheim and Drummond have utilised arsenic chloride, trichloracetic acid, dimethylsulphate, etc., for a similar purpose, and have found that the intensity of the blue colour runs parallel with the product's potency when tested on animals, in the case of both butter and cod-liver oil. Incidentally it may be mentioned that the antirachitic factor, in the form of cholesterol activated by exposure to ultraviolet light, does not give any colour with these reagents, a further confirmation of the distinctness of vitamins A and D. The test is very delicate, the cholesterol free unsaponifiable fraction giving it in a dilution of one in two million. The colour is discharged by a number of substances, including alcohol and ether.

One point may be referred to before leaving the work of the Japanese investigators, and that is that they have found their products toxic to rats in doses of about 10 mgm. a day. The possibility that this might be due to some poisonous impurity, perhaps introduced during the requisite chemical manipulations, does not appear to have been considered. It is obvious that the value of their conclusions will be considerably enhanced when the work has been repeated—and confirmed—by independent observers.

The relation of light to the fat-soluble vitamins has not yet been completely elucidated, but it appears from the evidence available that it produces synthesis of both the growth-promoting and antirachitic factors in plants, but in animals only influences the latter. Plants grown in the dark produce no vitamin A, but even one day's exposure to light is sufficient to cause its appearance: at the same time the lipochrome pigments are developed (K. H. Coward, *ibid.*). The relation of ultra-violet light to the antirachitic factor in plants has been little studied, since both factors usually appear to occur together: in animals, light does not cause any synthesis of vitamin A, but may influence the production of the antirachitic factor, for example, by activating the cholesterol in the skin. Whether this is the case or not, the improvement in calcification in rickets is probably in part due to an increased calcium absorption; since in other conditions in which there is a drain on the calcium of the body, for example, in lactation, exposure of the animal to ultra-violet light results in increased calcium absorption and retention (see the experiments on goats by J. B. Orr, H. E. Magee, and J. M. Henderson, *Biochem. Journ.*, 1925, vol. 19, p. 569).

A further factor to be considered in this increased retention of calcium is the influence of small quantities of iodine in the diet. F. C. Kelly (*ibid.*, p. 559) has shown that this addition to the diet of the growing pig produces an increased retention of nitrogen, phosphorus, and calcium, and points out that cod-liver oil is a rich source of this element. Iodine is necessary for the production of the thyroid hormone, which is itself essential for growth, but the relation, if any, between this secretion and the growth vitamins is at present unknown.

Whether light has any influence on the other vitamins is at present doubtful. In fact, so far as vitamin C is concerned, P. Eggleton and L. T. Harris (*Brit. Med. Journ.*, 1925, vol. 2, p. 989) have recently shown that oats germinated in the dark produce the vitamin in proportion to the amount of growth occurring; moreover, ultra-violet light cannot prevent or cure experimental scurvy in guinea-pigs on a scorbutic diet. Hence it cannot replace an adequate supply of this vitamin in the food.

Less is known of the chemical nature of the water-soluble vitamins than of that of the fat-soluble. S. S. Zilva (*Biochem. Journ.*, 1925, vol. 19, p. 589) has obtained vitamin C in a concentrated condition from orange and swede juice. The nitrogen content of this fraction was only 1-2 mgm. per cent., of which about half was amino and amide nitrogen; the latter could be destroyed without interference with the potency of the preparation. R. A. Peters (*ibid.*, 1924, vol. 18, p. 858) has obtained a somewhat similar result with a concentrated solution of vitamin B extracted from yeast; nitrous acid does not destroy it, as is the case with primary and many secondary amines. Working with H. W. Kinnersley, he has succeeded in purifying the yeast extract still further, until only 0·084 mgm. is necessary to cure symptoms of polyneuritis in a pigeon (*ibid.*, 1925, vol. 19, p. 820). Regular doses given to a bird on a polished rice diet are capable of preventing the appearance of symptoms without, however, maintaining its weight. Now vitamin B is essential for growth and maintenance of weight in rats, so that the authors are led by their results to suggest that the factor which cures and prevents polyneuritis in pigeons may be different from the one which is necessary for growth and maintenance of weight. It is possible, however, that the continued loss of weight without symptoms may be due to the deficiency of the polished rice diet in some other material.

It has been known for some time that excessive amounts of carbohydrate food hasten the onset of symptoms in pigeons. In examining the relationship between vitamin B and carbohydrate metabolism, P. Eggleton and L. Gross (*ibid.*, 1925, vol. 19, p. 633) have found that deprivation of vitamin B in rats leads in about a month to a fall in the blood-sugar, together with a gradual disappearance of glycogen from the liver; at the same time Kinnersley and Peters noticed that the convulsions of polyneuritic pigeons occurred at low temperatures, whilst removal of the birds to the warmth of the laboratory produced a temporary improvement. Now it is known that in mice the convulsions produced by insulin only occur regularly if the animals are kept at an external temperature so high as 37° C. At first sight the two observations appear opposed; but the condition of the experimental animals is fundamentally different: the mice have glycogen in their livers, whilst the pigeons probably do not. Hence cold in the former, stimulating glycogenolysis, acts against the insulin injected by producing a flow of sugar into the blood and thus prevents hypoglycæmic symptoms, whilst in the latter this cannot occur owing to the paucity of glycogen in the liver. At the same time, the cold increases the metabolism of the muscles, leading to withdrawal of sugar from the blood, which cannot be replaced, thus producing convulsions: warmth would diminish the demand for sugar and allow the blood-sugar to be restored to a more normal level. Some such hypothesis may be useful in correlating the various observations which have been recorded.

In conclusion, attention may be directed to some recent work in connexion with vitamin E, first described by Evans and Bishop a few years ago. It was observed that rats on certain synthetic diets, chiefly those in which the protein was supplied by casein, became sterile in course of time: any offspring of these rats obtained before sterility occurred were sterile from birth. In the female the ovaries are normal, the sterility being shown by absorption of the embryos late in gestation. In the male, on the other hand, the sterility is produced by degeneration of the testes themselves: a full description of the histological changes involved has been given by K. E. Mason (*Proc. Nat. Acad. Sci.*, *U.S.A.*, 1925, vol. 11, p. 377). Degeneration begins about two months after the commencement of the diet, and recovery only occurs when the vitamin is given if some normal testicular tissue is still in existence.

The distribution of the vitamin E and its properties are considered in more detail by H. M. Evans and G. O. Burr (*ibid.*, 1925, vol. 11, pp. 334 and 378). It is fat soluble, and its richest source is the oil expressed from the germ of wheat: it occurs also in oats, corn, lettuce, alfalfa, etc.; in small amounts in animal tissues including milk, and also in moderate amount in the vegetable oils. Cod-liver oil contains little. It is very stable and can be distilled in superheated steam; it occurs in the unsaponifiable fraction of the oil, but is not precipitated by digitonin: it does not contain nitrogen, sulphur, phosphorus, or the halogens. A single dose of 5 mgm. of the concentrated product by mouth or subcutaneously to a female rat suffices for the production of a normal litter, whilst 0·3 mgm. daily prevents male sterility. It appears to be stored in the body to a considerable extent, but is used up in the ordinary processes of metabolism quite apart from pregnancy. In some of its properties, therefore, it resembles the other fat soluble vitamins, but in its distribution, and in the fact that normal growth occurs in its absence, it is sharply differentiated from them.

News and Views.

AT a conference on March 25, held by the principal broadcasting organisations, representatives from twenty European countries took part. A new scheme for the redistribution of wave-lengths in Europe was submitted and provisionally approved. The details of the scheme will now be considered by the various interested organisations from the point of view of local difficulties. Suggested amendments will be considered by the Committee of the Office International of Radiophonie, and a final scheme will be drawn up for the approval of the various Governments concerned. The scheme divides broadcasting stations into two classes. The first class consists of those capable of guaranteeing good reception at long ranges. They receive an 'exclusive' wave-length, but every country receives at least one exclusive wave-length. The other class consists of low-power stations for the use of local listeners only. All this class will work on a common wave-length. Experiments have shown that each of these small stations can work without practical interference from the other stations using the same wave-length. To ensure satisfactory results it is absolutely necessary that the same standard type of wave-metre should be used by all the stations. This problem is being considered by a technical committee at Brussels under M. Raymond Braillard. No wave-lengths less than 200 metres have been allotted, and great pains have been taken to avoid unnecessary changes in wave-lengths already in use. It will be seen that the proposed solution is, perhaps unavoidably, not a perfect one. The ideal solution would be one in which every listener with a good valve set would be able to listen in to many of the small stations in Europe. If they all have a common wave-length this would be impossible In the course of other meetings held at Geneva, committees were formed to consider pressing international broadcasting problems with the object of finding practical solutions.

THE Czeckoslovak Academy of Agriculture, of comparatively recent formation, is seeking to establish and consolidate international relations for the benefit of agriculture in its country. The latest number of the *Věstník* (Ročnik I., Čislo 9-10) gives reports of papers read at the general meeting of the Academy, with summaries in French, German or English. The address of Dr. Julian Stoklasa on the nitrogen problem in the Czeckoslovak republic is given in four languages, rendering it accessible to a wide circle of readers. The problem is acute, but is receiving much careful attention. The yearly consumption of nitrogen is only 2·5 kilogm. per hectare compared with 20 kilogm. per hectare in Germany, and it is calculated that very heavy losses have been incurred during the last seven years owing to this deficiency, as the yearly harvest is held to abstract 40 kilogm. nitrogen from each hectare of soil, on an average. The production of synthetic nitrogenous manures on a large scale is under careful consideration. Since 1923 the work has been under the direction of the Ministries of National Defence, Public Works and Agriculture, which created the Inter-ministerial Nitrogen Committee. It is recognised that the country is too dependent on imported food stuffs owing to the failure of agriculture to attain the necessary economic intensity. The chief causes of failure are the high costs and the scarcity of certain means of production, nitrogenous fertilisers being a prominent example, more than 60,000,000 kilogm having recently been imported yearly, chiefly as Chile saltpetre. As a further means for improving the knowledge and status of agriculture in Czeckoslovakia, the Academy has set up commissions for publishing an agricultural encyclopædia and a bibliography, and for the establishment of a central library and reading-room in which would be concentrated all Czeckoslovak and Slavonic agricultural literature, together with the most important world literature on the subject.

ONE cannot imagine a more eloquent series of tributes than those which, lead by M. Painlevé, were pronounced over the grave of the late Camille Flammarion, which have now been issued in permanent form, admirably reprinted on art paper, from *L'Astronomie*, the bulletin of the Astronomical Society of France, of which Flammarion was the founder. The book also contains an account of the funeral ceremonies, and a selection from thousands of letters received from astronomical observatories and scientific institutions at home and abroad, and from public and private individuals. A lengthy and complete discourse on the life and work of Flammarion is included from the facile pen of M. Emile Touchet, who was long associated with the dead "maître" in the administration of the largest of all astronomical societies. Several portraits of Flammarion at various periods of his life are included, the last of which, taken shortly before death, is a characteristic picture. For an authentic pronouncement on the life and work of an inspiring French astronomer, one need not go past this little publication, coming as it does from the fount of his astronomical activity. The book can be obtained from the headquarters of the Society at 28 Rue Serpente, Paris. Flammarion was a great admirer and user of British scientific publications, particularly NATURE, and it is interesting to learn on the authority of his widow that the last piece of literary work he accomplished, actually on the day of his death, was the translation of a note on "Ancient Clepsydræ" from our issue of October 25, 1924. This he intended for reproduction in *L'Astronomie*. Shortly after this was completed he walked to the window, commented upon the beautiful day and the loveliness of his garden, and collapsed into the arms of Madame Flammarion. The last prospect he beheld was the extensive view over the Seine which he asked the writer of this paragraph to photograph for him one magnificent summer Sunday afternoon many years ago. Flammarion was proud of that view.

AT a meeting of the Scientific, Technical, and Trade Circle of the Institute of Journalists, held on March 30, a summary of the aims and objects of the Optical Convention was given by Mr. F. Twyman (chairman of the Executive Committee), Sir Richard Paget (Hon. Treasurer), and Prof. Cheshire. In thus inviting the co-operation of the members of the Circle the precedent set in connexion with the British Empire Exhibition a couple of years ago was followed. Mr. Twyman enumerated some of the very wide range of instruments and apparatus in which optical lenses and prisms are necessary, and Prof. Cheshire, who gave an account of some of his experiences when acting as Director of Optical Munitions during the War, directed attention to the vital importance of an adequate home supply of optical glass in modern warfare, and the necessity of encouraging and developing the British optical industry in time of peace. Sir Richard Paget gave an entertaining account of the various optical illusions and exhibits at the Convention likely to be of popular interest. These include many ingenious and novel devices as well as demonstrations of lantern projection in natural colours and other processes of great practical importance. In this respect the organisers are following the lead of early pioneers in science who did not disdain to kindle public interest by the exhibition of odd contrivances and striking effects. In early scientific entertainments 'optical illusions' often played a considerable part.

"CAPE to Cairo," Major C. Court Treatt's kinematograph film of a journey by motor car through Africa from south to north, now showing at the Regent Street Polytechnic, is a record of a remarkable feat of organisation and endurance. The expedition, with Major Treatt as leader, consisted of Mrs. Treatt, Mr. F C. Law, Mr. Errol Hinds, and Mr. T. A. Glover, the photographer who accompanied Major Angus Buchanan in his journey across the Sahara A distance of 13,000 miles was covered in sixteen months; but a mere statement of time and distance can convey no adequate conception of what the journey involved. In the early stages, while traversing Rhodesia, they were caught by the rains. The cars were constantly bogged in the deep mud of the roads, while the rivers were so swollen as to be almost impassable. Throughout, the rivers were the most serious obstacle. When they reached the Nile, it was only by towing the cars across the river under water that the expedition was saved from failure. The film records some native dances—a war dance in a Uganda village and a Dinka dance being particularly interesting—and gives a good idea of the varying types of African scenery. Special mention must be made of the pictures of a herd of buffaloes and a really remarkable and exceptional series of the Zambesi falls. The part played by Mrs. Treatt in securing friendly relations with the natives is an object lesson of the valuable work which can be accomplished by a woman, and in some matters by a woman only, in anthropological and geographical exploration.

In the course of an account of recent excavations at Beisan in Palestine, contributed to the *Times* of April 4 by Mr. Allan Rowe, Field Director of the Philadelphia University Museum Expedition, reference is made to an interesting find, and a suggestion made as to its meaning and use, which will appeal to all readers of Sir James Frazer's "Golden Bough." The object in question is a hollow circular ring of clay, to the top of which are attached several jars and animal heads. The jars have holes in the base which connect with the hollow inside the ring. Another example such as this was found some years ago at Megiddol and a derivative, much later in date, was found at Naukratis in the temple of Aphrodite. It is suggested that these objects are the flower stands known to have been in use in Syrian temples, and that they may be the actual "Gardens of Adonis," the baskets or pots in which various kinds of seeds or grain were planted and tended by women for a period of eight days, when they were thrown into a river or stream with an image of the god. It will be remembered that Sir James Frazer, in his "Adonis, Attis and Osiris," suggests that the rite was intended as a charm to secure abundance of rain or water for the crops, and adduces a number of analogous customs from various parts of the world to support his view.

For several years past an annual inter-university conference of metallurgical students has been held, attended by delegates from the principal universities and technical colleges in Great Britain, for the purpose of discussing questions concerning the training and prospects of professional metallurgists. At the conference held in Birmingham on February 19 and 20 last, the subject for discussion was the place of the metallurgical student in industry. There was general agreement among the speakers as to the necessity of combining works training with the academic course, for which purpose the vacations could be partly utilised. Graduates on entering a works should at once be given a self-supporting wage, the system of apprenticeship being undesirable. On the other hand, the graduate should enter on his duties with a due sense of his inexperience and a proper respect for the practical knowledge of the technical man. It was considered that a trained metallurgist should not become a routine chemist, but should be regarded as having a special function. Some speakers urged the giving of more attention to the commercial side of industry, and to such subjects as works organisation and management, instruction in those subjects being given preferably by industrialists. Copies of the report may be obtained free on application to Mr. W. L. Kent, Metallurgical Society of the University, Birmingham.

The Association of Special Libraries and Information Bureaux, which held a conference at Oxford last autumn (Nature, October 10 and November 14), has now decided to proceed with a formal constitution and the enrolment of members. The inaugural meeting was held at the Institution of Mechanical Engineers on March 29 and was well attended. Mr. J. G. Pearce, director of the British Cast Iron Research Association, presided. The Association has planned a third conference, to be held at Balliol College, Oxford, on September 24-27, at which the draft constitution will be submitted to the members. The first work of the Association, which is one of some magnitude, is the preparation of a Directory of Special Libraries and Information Bureaux in the United Kingdom, which should contain in a suitably classified form a guide to existing sources of reference. The Carnegie United Kingdom Trust, which has already generously supported the Association, has promised to finance the preparation of the Directory at an estimated cost of 2000*l*., and with the wide interest already taken in the Association by delegates from learned societies and large industrial corporations, it is hoped that the difficulties of editing such a volume can be overcome.

The King has approved that the Royal Commission on Agriculture in India should be composed of the following: The Most Hon. the Marquess of Linlithgow (chairman); Mr. H. Calvert; Prof. N. Gangulee, professor of agriculture and rural economy, University of Calcutta; Dr. L. K. Hyder, professor of economics, University of Aligarh; Mr. B. S. Kamat; Sir Henry Staveley Lawrence; Sir James MacKenna; Sir Thomas Middleton; The Rajah of Parlakimedi; Sir Ganga Ram. The appointment of a Royal Commission, "generally to examine and report on the present conditions of agricultural and rural economy in British India," was announced by Lord Reading at the opening of the Indian Legislature on January 20. The terms of reference go on to point out particular directions in which investigations are to be pursued. The scope of the inquiry was discussed in these columns in our issue of January 30, p. 166.

Among the gifts for scientific purposes made by the late Prince Albert of Monaco in his will was a sum of a million francs to the Paris Academy of Sciences for the provision of a biennial prize (Nature, October 14, 1922, p. 524). The first award of this prize has been made to Dr. Charcot, who will thus be enabled to improve the scientific equipment of his vessel, the *Pourquoi Pas*! It is appropriate that the first to benefit under the bequest should be Dr. Charcot, for Prince Albert, himself a keen scientific worker, carried out many notable investigations in physical and biological oceanography.

DR. P. CHALMERS MITCHELL, secretary of the Zoological Society of London, will deliver the Huxley Memorial Lecture at the Imperial College of Science and Technology on May 4 at 5 P.M., taking as his subject "Logic and Law in Biology."

THE proceeds of the Daniel-Pidgeon Fund of the Geological Society of London for 1926 have been awarded to Dr. David Williams, who proposes to investigate the geology of the country between Snowdon and the Carnedds.

WE are asked to state that the meeting of the Chemical Society which had been arranged for Thursday, April 15, has been postponed until the usual hour on Thursday, April 22.

THE fifth Hurter and Driffield memorial lecture of the Royal Photographic Society of Great Britain will be delivered on Tuesday, April 20, at 7 o'clock, by M. Charles Fabry. The subject will be "The Photographic Plate as a Measuring Instrument for Visible and Invisible Radiations."

A MEETING of firms interested in the formation of a research association for the paint, colour, and varnish industries will be held at the London Chamber of Commerce, Cannon Street, E.C., on Wednesday, April 14, at 11 A.M. An invitation to be present is given to members of companies interested in these industries.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: A resident tutor in economics in the University of Bristol—The Registrar (April 20). A lecturer in the department of electrical engineering of Bradford Technical College—The Principal (April 21). A lecturer in botany in the University of Bristol—The Registrar (April 30). An assistant plant breeder under the Department of Agriculture and Forests of the Sudan Government—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1 (May 7). A professor of physiology at St. Bartholomew's Hospital Medical College — The Academic Registrar, University of London, South Kensington, S.W.7 (May 20). A laboratory assistant in the Biochemical Department of the Wellcome Physiological Research Laboratories, Beckenham—The Director. A chief physics master at Shrewsbury School—The Headmaster's Secretary, The School House, Shrewsbury.

Our Astronomical Column.

THE DISTRIBUTION OF O-STARS.—An article by B. Gerasimovic, of Charkow Observatory, in *Astr. Nach.* 5420, deals with the galactic distribution of these stars. As is well known, they lie in very low galactic latitude and afford one of the best methods of obtaining the co-ordinates of the galactic plane, and the linear distance of the sun from it. The 144 O-stars in the Draper Catalogue (excluding those in the Magellanic Clouds) give for the galactic pole R.A. 189° 13′, N. Decl. 27° 22′ (equinox not stated, but presumably 1900), while the 78 planetary nebulæ in Curtis's Catalogue give R.A. 192° 13′, N. Decl. 28° 28′. The latter show a greater dispersion than the O-stars, which is shown to arise from wider scattering in space, not from greater proximity to us. The mean distance of the O-stars is taken as 770 parsecs after Wilson (Plaskett increases the distance to 900 parsecs), and the distance of the sun to the north of their mean plane is found to be 31 parsecs.

Further, it is shown that the angular width of the zone of O-stars is greatest in the direction of the anti-centre of the star-system (according to Kapteyn, R.A. $23^h\ 10^m$, N. Decl. 57°), where it amounts to 11°, being only 3° in the opposite direction. This is ascribed to the greater proximity of the zone in the former direction.

THE DISTRIBUTION OF RADIANT ENERGY OVER THE SUN'S DISC.—Bulletin No. 91 of the Aeronautical Institution of the Netherlands is devoted to a communication from the Heliophysical Institute at Utrecht, "The Distribution of the Energy over the Sun's Disc," by W. J. H. Moll, H. C. Burger, and J. van der Bilt. To avoid the disturbing effects of the lower atmosphere the authors set up their apparatus on the Gornergrat near Zermatt. They had the good luck to find next to the hotel a small house with brick walls, admirably suited for an observatory. The 'monochromator' with which the energy of any assigned wave-length was determined was provided with a linear vacuum-thermoelement, and was therefore more sensitive than the apparatus used by previous investigators. The slit of the monochromator was only 0·1 mm. wide. It was found that a sufficiently regular movement of the sun's image, 3 cm. in diameter, past the slit could not be obtained with a cœlostat. Regularity was achieved by using fixed mirrors and giving a steady motion to the lens by which the image was formed.

Final results are not yet available, but the authors claim that they were able to get trustworthy values of the distribution of the energy along about 99 per cent. of the sun's radius against Abbot's 95 per cent. Their values of the ratio of the energy to that at the centre of the disc are greater than Abbot's. The differences attain a maximum amount of about 2·5 per cent. at a distance from the sun's limb of about 8-hundredths of the radius. The discrepancy is attributed to the quicker response of the new apparatus. The general result, that the radiation in all parts of the spectrum falls off rapidly near the limb, is of course confirmed. The effect is most conspicuous in the shorter wave-lengths, so that the sun is yellowish towards the edge. At 5-hundredths of a radius from the limb the blue rays have only half their intensity at the centre and at 2-hundredths less than a quarter. The curves are in fact consistent with the hypothesis that the radiation falls to zero at the limb. It is to be hoped that further use will be made of the observatory on the Gornergrat. Independent measurements of the 'solar constant' might well be made there, for comparison with the determinations at the stations of the Smithsonian Institution in America.

Research Items.

A Tahitian Breast Ornament from Alaska.—Dr. H U. Hall discusses in the issue of the *Museum Journal* dated September last, the provenanoe of an object of exceptional interest recently acquired by the University Museum, Philadelphia. Although it was collected in an Indian village on Admiralty Island, Alaska, it is beyond question a feather breast ornament from Tahiti. Only seven of these are known to be in existence, three being in the British Museum. That they belonged to the highest chiefs is clear, since their adornments include red feathers, sacred to Oro the war god, which could be worn only by persons of this class. They are described by Cook under date September 8, 1777, and possibly, under missionary influence, had ceased to be used so early as 1825, or at any rate not much later. It is therefore improbable that this specimen was carried north by one of the whalers, who did not begin their voyages to the Arctic through Bering Strait until the late 'forties. It would seem most probable that it was taken to Alaska either by Cook or Vancouver, the probabilities favouring the latter. Among the Chilkat it was a clan object and regarded as very precious. It was known as 'raven cape.' The late owner said that the old leaders of her house had boasted of it as a possession which was uncommon It was regarded as the work of the people of another world Fragmentary traditions of its origin connect it with the coming of the white man, and refer it to a strange party who made a visit to the land " in company with the first man of the sun."

An Archæological Collection from Flagstaff, Arizona.—A number of archæological objects from graves found in Young's Cañon, near Flagstaff in Arizona, has recently been added to the U.S. National Museum, Washington. It is of special significance for the archæology of the south-western United States, partly because some of the objects are unique; partly because few antiquities have been obtained from this area. The collection was made by Mr. J. C. Clarke in the course of road-making operations, and consists principally of pottery, red, gray, dark, and painted ware, shell bracelets, armlets, and finger rings, a few bone objects, needles, bodkins, and the like. Two rare specimens of polished bone with incised decoration were evidently ornaments for the hair as they were found on a cranium. Cremation was practised and calcined human bones were found in mortuary vessels or burial urns. Mr. J. W. Fewkes, who describes the collection in *Smithsonian Miscellaneous Collections*, Vol. 77, No. 10, directs attention in particular to the pottery, of which the decorative designs are purely geometric, none showing naturalistic forms of men or animals. None is perforated or ceremonially 'killed.' One object is exceptional, a black and white ware ladle, of which the sides and end of the handle are pinched up to form a cradle. This contains a small clay figurine. Similar figurines have been found higher up the Little Colorado, suggesting that the cradle-handled ladle, though rare, was known in Pueblo households. The pottery as a whole resembles the pre-puebloan of the region north of the Hopi Pueblos—a culture which probably at one time spread over the whole of what is now Arizona and is now best represented on the Lower San Juan in the region called Takonabi.

The Atmosphere and Human Comfort.—The *Monthly Weather Review* for October last has an article on "The Relation of the Atmosphere to Human Comfort," by Dr C. F Brooks of Clark University. The journal also contains other articles on the same subject, treating different branches, but all have general reference to America The work is allied to that undertaken by Prof. Leonard Hill in Great Britain, but an attempt is made to push the study further and to reduce it to mathematical form in order to find a basis by which weather might be classified according to its relation to human comfort. With data of heat emission, heat production, and comfort, Dr. Brooks considers it possible to construct tables which will show for any weather conditions approximately the rate at which a man will cool. We need tables showing for any kind of weather the feeling of cooling which a man will experience under any degree of activity and in any kind of clothing. More calorimetric observations of the actual cooling and heating of man are required. The author hopes that the discussion will be helpful as a pioneering effort.

Asymmetry in Microscopic Organisms.—In his presidential address to the Quekett Microscopical Club (*Journ. Quekett Micr. Club*, Nov. 1925), Mr. D. J. Scourfield directs attention to asymmetry in microscopic organisms and to the need for observations on the functioning of asymmetrical structures in order to throw light on the vexed question of adaptations. Among the rotifers, the Rattulidæ present a twisting of the body so that practically every part is involved in the asymmetry. Among the Bdelloid rotifers the jaws occasionally show slight differences, and in this group there are two ovaries which function alternately, while in other rotifers there is only one ovary. Mr. Scourfield recalls examples of asymmetry in some Crustacea and refers to the occurrence of androgynous individuals of Daphnia, rightly urging the desirability for carefully recording the condition of such examples. He enters a plea for experimental research in the cultivation of microscopic organisms under varied conditions, and we may suggest to the keen amateur that the tracing of the subsequent history of such androgynous specimens which, *e.g.*, exhibit a male antenna on one side and a female antenna on the other, would form an interesting study.

Beating of the Early Embryonic Heart.—The Report of the Department of Embryology of the Carnegie Institution of Washington (from Year Book No. 24), which is located in Baltimore, shows the wide range of investigations in progress, *e.g.* on cleavage stages in the pig, the origin of the notochord, the development of the blood-cells, and a re-analysis of the different types of cells by the aid of staining living blood smears, the study of early human embryos—a well-preserved 7-somite embryo has been carefully investigated—and a number of other lines. Of interest to all biologists is P. N. Johnstone's work on the heart of living chick embryos. In addition to making observations on the morphology of the living embryonic heart he has studied the origin of the first pulsations, and finds they first appear at the 10-somite stage in the primitive ventricle. Starting at a definite spot on the right border of the ventricle, the beating area spreads until the entire ventricle is engaged in rhythmic contractions. It is some time later that the pulsations begin in the primitive sinus venosus, so that at the outset the sinus venosus does not serve as a "pacemaker" for the ventricle. The author further confirmed this by placing a ligature between them which did not alter the rhythm of the ventricle, but later, by the fourth day of development, such a ligature produces heart block, showing that the rôle of pacemaker or rhythm control has then shifted to the sinus venosus. Mr. Johnstone devised a method for stimulating these small hearts electrically, and found that the earliest period at which the chick's heart can be influenced by electrical stimulation is the middle of the third day: that is, long after the atrium, permanent ventricle and bulbus arteriosus have become functionally active.

The Classification of Insects.—*Bull. 162, Agri. Research Inst., Pusa* (1926), is a publication of 101 pages devoted to "Tentative Keys to the Orders and Families of Indian Insects." Its author, Mr. T. Bainbrigge Fletcher, has compiled this synopsis in order to meet a long-standing want for a modern guide to the detailed classification of Indian insects. Present-day tendencies are towards the recognition of an increasing number of orders and families among insects, and it has become progressively difficult for isolated workers, in a country so extensive as India, to keep in touch with recent changes. Mr. Fletcher has, to a large extent, followed the classification of Brues and Melander (whose system is based upon that of Handlirsch), and recognises thirty-two separate orders. In many cases it is still largely a matter of opinion as to what criteria are to be accepted as being of ordinal value. We note that the author has wisely united the Mallophaga and Pediculina (Siphunculata) into the single order Anoplura; but, on the other hand, the Zoraptera and Psocina, which are closely related to each other, are retained as separate orders. The increasing number of families of the larger orders is the outcome of specialisation and intensive study; and, in India alone, there are 86 families in the Coleoptera, 75 in Hymenoptera, and 73 in Lepidoptera. The fact that only a small number of families do not find a place in these keys (since they are unrepresented in India) is a feature commending the Bulletin to workers in other lands besides those in the country for which it is written.

Winsconsin Algæ.—Of great interest to algologists is the publication of the second part of Prof. G. M. Smith's "Phytoplankton of the Inland Lakes of Winsconsin" (*Bull. Univ. Winsconsin, Serial No. 1270*, pp. 227, 1924). This volume deals with the Desmidiaceæ. It quite reaches the high standard set by the earlier publication, and it is a necessary work of reference to all interested in this subject. Four new species and seventeen new varieties are described, most of them belonging to the genus Staurastrum. Among a small number of new combinations is the transfer of *Dictyocystis Hitchcockii* (Wolle) Lagerheim to Cosmocladium. The work of European authorities, notably West and Borge, has been thoroughly assimilated and collated.

The Swamp Cypress of China.—At a meeting of the Royal Irish Academy on March 16, a paper was read by Prof. A. Henry, giving a detailed account with photographs and drawings of the Chinese swamp cypress, known to science as *Glyptostrobus pensilis*. This species has died out in the wild state, and is only known in cultivation in two restricted localities around Canton and Foochow. It has been preserved from extinction by the superstitious beliefs of the peasants, who plant it on the north side of villages to bring luck, and amidst rice-fields to increase the crop. Adapted to wet, marshy situations, it develops peculiar curved "knees," which are woody growths from the roots, projecting above the ground. The function of the knees is to enable the roots to breathe, whenever the soil happens to be inundated. The genus is a very ancient type, and its fossil remains have been found throughout the Tertiary era, widely spread over the northern hemisphere in North America, Europe and Asia, extending as far north as Spitsbergen, Greenland and Alaska. Its twigs and leaves have been gathered in the Eocene beds at Ardtun in the Isle of Mull, in company with similar remains of two other genera, Ginkgo and Cryptomeria, all three being now represented in China by three living species, which can scarcely be distinguished from those that flourished at the beginning of the Tertiary era. Ginkgo is also unknown at the present time in the wild state, and owes its preservation to the Buddhist priests who plant it around their temples. Prof A. Henry, who was assisted in the microscopical work and drawings by Mrs Marion McIntyre, gave in addition a comparative account of the American swamp cypress Taxodium, which is much better known to science than Glyptostrobus. The photographs of the latter, obtained recently from China, are the first to be published of this interesting tree.

Cotton in Tanganyika.—The report of the Department of Agriculture of the Tanganyika Territory for 1924–25 shows, among other developments, a remarkable extension of cotton-growing among the natives. The Department is the only legal source of cotton-seed supply to natives and the chief source to non-native planters. Figures show an increase in seed distribution to natives from 481 tons in 1923 to 1594 tons in 1925. The lint production has increased by 64 per cent. in the last year. Furthermore, it is of interest to note the general superiority, as judged from brokers' reports, of the native-grown cotton over that raised on non-native estates. Extensive experiments are being carried out on the time of sowing in relation to rainfall and on the spacing that gives the best results. Studies of the pink bollworm of cotton, which has apparently been known in Tanganyika since the Germans imported seed in 1898, leads to the probability that it is not indigenous but was introduced from India through Egypt. With the strict control on the movements of seed, it is hoped that this pest may be kept in hand.

Surveys in Somaliland.—In the January-February number of the *Bolletino* of the Royal Italian Geographical Society, Messrs. G. Stefanini and N. Puccioni give a long account of the expedition to Italian Somaliland in 1924, undertaken by Mr. Stefanini under the auspices of the Italian Government and the Italian Geographical Society. A map on a scale of 1 to 1,500,000 accompanies the paper and covers the south-western part of the country as far as the Juba river. A number of short papers dealing with the general scientific results of the expedition, in particular anthropology, are appended.

Historical Russian Diamonds.—The jewels of the "Russian Diamond Treasure" have recently been thoroughly examined by the distinguished mineralogist Dr. A. Fersman, and in a series of papers of historical as well as scientific interest, many of the legends and misconceptions that have crept into the descriptive literature of these stones are corrected (*Bull. de l'Acad. des Sciences de l'U.S.S.R.*, 1922, 1925 and 1926). The "Shah" diamond is a remarkable elongated octahedron of Indian origin, which bears engraved inscriptions of three different dates. Soon after the first engraving in 1591 it passed into the possession of the Great Moguls, and in 1665 it was seen by Tavernier in the palace of Aureng-Zeb. In 1739 it was seized by the Shah Nadir and carried from Delhi to Persia. In 1829 a Russian diplomatic agent was murdered in Teheran, and to conciliate the Tsar the famous gem was presented to Russia. The "Orlov" diamond is the largest of all the old stones of Golconda, and it is now identified by Fersman as the "Great Mogul," also seen by Tavernier in 1665. The Shah Nadir possessed this beautiful gem for some time after the conquest of Delhi, and with the "Koh-i-noor" it was mounted in the Persian throne. The "Orlov" was stolen and passed through various adventures until 1773, when it was purchased by Prince Orlov and presented to Catherine II. Since then it has held pride of place in the sceptre of the late Tsars. The "Koh-i-noor," which has often been described as the "Great Mogul," lost its historical Hindu form in 1862, when it was re-cut, after having been presented by the East India Company to Queen Victoria in 1850.

PLATINUM DEPOSITS IN SOUTH AFRICA.—In the *Trans. Geol. Soc. S. Africa*, vol. 28, 1925, pp. 83-133, Dr. P. A. Wagner describes the platinum occurrences in the norite zone of the Bushveld complex. Taken as a whole, they constitute the world's greatest primary concentration of that metal, the localities of the deposits being scattered along the norite periphery for nearly 400 miles. The distribution indicates that extreme magnetic differentiation was essential for platinum concentration It is shown that in dunite, unusual basicity of the residual fractions, together with the presence of fluorine, were the most probable conditions essential to the formation of rich deposits. The metal also occurs with magmatic nickel-copper-iron sulphides which are indigenous to the rocks in which they occur. The sheets of sulphidic rocks are invariably floored and roofed by anorthosite, suggesting a preliminary necessity for the separation of calcic felspar, and indicating a type of differentiation dependent not on gravity alone, but more particularly on gas pressure Here sulphurous gases were presumably responsible both for the peculiar rock differentiation and for the extraction and concentration of the platinum. Where the sulphidic magmas were brought into contact with dolomites or sheared banded ironstones, contact deposits of platinum-bearing sulphides were formed. The paper is a most valuable contribution both to economic geology and to the theoretical aspects (which still remain confused) of ore-genesis and magmatic differentiation. The views of W. H. Goodchild and J. E. Spurr on these topics are here supported by much of the newly recorded evidence.

THE JAPANESE EARTHQUAKE OF 1923.—Continuing his investigation of the great Kwanto earthquake, Prof. T Ogawa now presents evidence in favour of the hypothesis of magmatic injection, and adverse to the alternative tectonic theory (*Jap Journ of Geol. and Geog*, vol 3, No 3). Omori determined the mean depth of the hypocentra of shocks in the Kwanto region as 34·5 km., and Ogawa combines this result with Shida's conclusion that the 1923 earthquake began as a deep-seated fracture. The depth of fracture is so great that an injection of magma seems to be implied as the underlying cause, particularly as the depth is also that deduced from other evidence as the upper boundary of the magmatic zone. On plotting the epicentra of all the great shocks of the region since the twelfth century, they are found to coincide with a zone of eruptive rocks. It is suggested that the association of volcanic eruptions with great earthquakes—recognised in South America long ago by Humboldt and Darwin—is a genetic one. The extraordinary 'depressions' and 'upheavals' of Sagami Bay revealed after the 1923 earthquake provided evidence for the tectonic theory, but Ogawa shows that this is not conclusive He interprets the changes of level as due to the shifting of sediments of mobile consistency by a process of submarine gliding initiated by the earthquake and intensified by the long waves of the *Tsunami*. The new explanation further accounts for the fact that the alleged crustal movements are limited to the floor of Sagami Bay and do not extend to the surrounding land.

THE LAW OF FORCE WITHIN THE ATOM.—In two papers which were communicated to the Vienna Academy of Sciences in 1924 and have now been issued as parts 9 and 10 of volume 133 of the *Sitzungsberichte*, Dr. Hans Pettersson describes his observations of the number and ranges of the H-particles ejected from carbon, aluminium, magnesium, nickel, and copper at angles exceeding 150° from the paths of the α-particles used in bombarding the atoms. He finds that the numbers are less than would be expected on the current theory, and concludes that some of the bombarding particles are retained by the nucleus. He also shows that the change from repulsion of like charges by each other to attraction at atomic distances, which observations have rendered probable, may be explained by the displacement of the negative charges of the nucleus towards, and of the positive away from, the approaching α-particle without departing from Coulomb's law. On this theory the surface of zero force has a radius for carbon of 1·34, for aluminium of 1·22, and for gold of 1·09 times the radius of the nucleus.

THE SULPHUR COMPOUNDS OF KIMMERIDGE SHALE OIL.—Technical literature contains numerous references to the sulphur content of Kimmeridge shale oil, and numerous unsuccessful attempts have been made to eliminate this undesirable constituent. Most of these trials have proceeded, however, without any knowledge of the form in which the sulphur occurs. It was left to Messrs. F. Challenger, J. Haslam, R. J. Bramhall, and J. Walkden to determine the problem, and the results of their work were presented to the Institution of Petroleum Technologists on February 9 last. So far back as 1885 Victor Meyer established the presence of thiophen and its homologues in coal tar, a factor having direct bearing on the sulphur condition in shale oil; subsequent researches of Mabery on American petroleum, Thierry on Persian crude oil, and Scheibler on shale oil from the Tyrol and south of France, led to the recognition of thiophen derivatives in these oils. In their investigation the authors paid special attention to that portion of the Kimmeridge oil volatile in steam, representing an average of 30 per cent., and successive fractions of the oil were examined independently. The fractions tested were—(i.) 93°, (ii.) 109°-117°, (iii.) 117°-126°, (iv.) 132°-140°, (v.) 158°-167°, (vi.) 105-115/27 mm, (vii.) 115-140/27 mm. From (i.) a small amount of thiophenmercurichloride was obtained on treating part of the fraction with alcohol, mercuric chloride, and sodium acetate. In the case of (ii.) a large amount of 2-methylthiophen was isolated; the presence of 2-ethylthiophen and 2 : 3-dimethylthiophen (2 : 3-thioxen) was established for (iv). Fraction (v.) yielded a complex derivative, not yet definitely identified, approximating to the propyl-, methylethyl-, or trimethylthiophen. From the fraction (vi.) naphthalene and thionaphthem were obtained by use of picric acid and mercuric acetate; the compound thiophthen is also suspected in this portion of the oil. As will be noted, these products are all derivatives of thiophen, but the authors have also succeeded in establishing the presence of tetramethylene sulphide and similar derivatives. These results may lead to the formulation of a successful desulphurisation process.

Dutch Pendulum Observations in a Submarine with a New Apparatus.

AT the request of the Dutch Geodetic Committee, the Minister of Marine has once more allowed Dr. Vening Meinesz to make pendulum observations on board a submarine of the Royal Navy, bound for Java, on the voyage from Helder to Alexandria[1] He left Helder on October 15 on board H.M. Submarine K XI, and arrived at Alexandria on November 12, after having touched at Sevilla and Tunis. On November 23 he embarked at Port Said on board the Dutch mail-steamer *Koningin der Nederlanden* and disembarked on December 5 at Amsterdam

The main object of the voyage was the trial of a new pendulum apparatus constructed on the lines described by Dr. Vening Meinesz in No 5, Janvier/Mars 1925, of the *Bulletin Géodésique*, the organ of the geodetic section of the Geodetic and Geophysic Union. With the consent of the Minister of "Waterstaat" and the director in chief of the Royal Meteorological Institute at de Bilt, Prof. Dr. E. van Everdingen, the apparatus was constructed in the mechanical workshop of this Institute by the chief instrument-maker, Mr L. L. M van Rest, with the co-operation of the assistant director, Dr C Schoute[2]

A detailed description of the apparatus with the necessary illustrations will appear in a publication of the Geodetic Committee, for the time being the following cursory description may suffice.

The whole apparatus consists of three parts: the support with the pendulums, the suspension apparatus and the recording apparatus.

The support contains three quarter-metre pendulums of the common Von Sterneck model, the same as were used on the first voyage. These are of brass, not of bronze as was stated erroneously in my former communication.

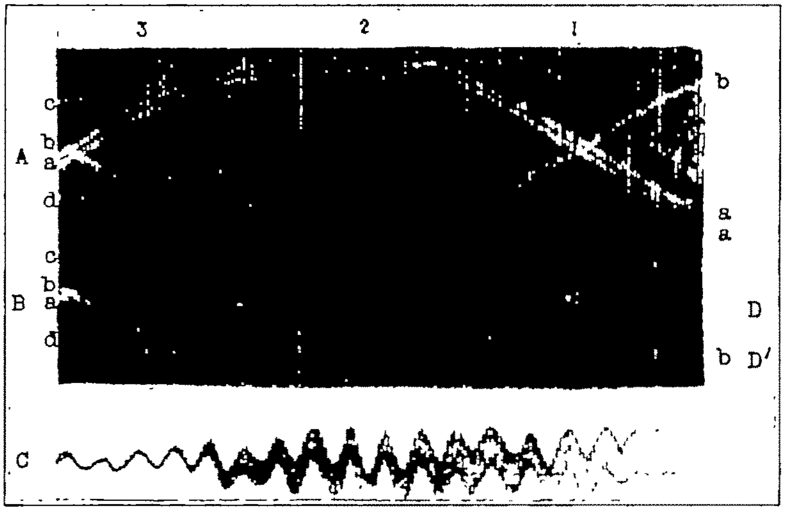

FIG. 1.—November 2, Tunis Harbour A and B, curves of hypothetical pendulums (overlapping) Time gaps showing four curves *a* and *b*, sidereal time (short period), *c* and *d*, mean time (long period) C curve of middle pendulum Inclination of plane of oscillation. D, damped pendulum, D′, undamped pendulum

The three pendulums are rendered as near as possible isochronous They oscillate in the same plane and can be set going simultaneously with an exactly adjustable amplitude. The oscillations are recorded on a moving photographic film by the light reflected by a mirror fixed to the pendulum, but not, as with the former apparatus, for each of these separately. The light-ray reaches first the mirror of the first pendulum, next that of the second. It records in this way the difference of the elongation angles. The result is that the film gives the curve of a hypothetical pendulum, of which the revolving vector is the difference of the vectors of the constituent pendulums As the disturbances of those, caused by the horizontal accelerations due to the movement of the vessel, are the same, their effect is eliminated from the hypothetical pendulum

In the same way, a second hypothetical pendulum is recorded by the third pendulum in combination with the second The two curves give two independent results, which control one another and increase the accuracy.

For the amplitude reductions of the observations, the movement of the second pendulum must be recorded separately; the ray which performs this is on its way reflected by a small, highly damped pendulum, of a construction devised by Dr Vening Meinesz, the plane of oscillation of which is parallel to that of the other pendulum. In this way the movement of the middle pendulum is recorded with respect to the vertical.

A second highly damped pendulum of the same construction, the plane of oscillation of which is perpendicular to the plane of the others, serves to record the inclination of this plane during the observations It was controlled by a small undamped pendulum, but the results proved that this control is not necessary

The changes of temperature within the apparatus during the observations are recorded by means of a metallic thermometer.

Before the rays of light enter the support, they pass a lens that makes them parallel. When leaving it they pass a second lens that collects on the film the constituents of every bundle of rays Within the apparatus each bundle is compelled to follow its path by a number of mirrors or prisms In every path there is one adjustable prism by which the distribution of the curves on the film can be regulated

Between the observations the pendulums are not to be removed, they can remain in the apparatus, even when the motion of the vessel is most violent. By turning a small handle the knives of the pendulums are lifted from the agate planes on which they oscillate during the observations. By moving a second handle the double cone at the lower end of each pendulum is fixed between four arms The fastening is strong, but elastic, in order to avoid the effect of shocks on the pendulums. The disposition is such, that when the pendulums are free it is impossible for any one to turn the handle that commands the arms below before the pendulums are lifted, or when the pendulums are fastened, to turn the handle that lowers them before the arms are removed

The brass top and base plates of the support are connected by strong vertical slabs, the top plate carries the pendulums, the fixed mirrors and prisms and the two lenses. The three agate planes on which the knife-edges of the pendulums rest lie in exactly the same plane, they have been ground and adjusted by the firm Hahn in Cassel (Germany). The base plate rests on three foot screws; parallel to the plane of oscillation of the pendulums a small level is affixed; the bubble is, during the observations, in constant movement owing to the rolling of the vessel, the pendulums must be set free the moment that the bubble is at zero, in order to begin the oscillations with the desired amplitude. Between the top and the base plate are placed a dummy pendulum with thermometer and a hair hygrometer.

---

[1] Particulars of the voyage on board H M. Submarine K II from Helder to Batavia in 1923 are given in NATURE of September 15 and December 1, 1923, and March 1 and May 3, 1924

[2] If geodetic offices in other countries should wish to purchase a similar apparatus, the "Nederlandsche Seintoestellenfabriek" at Hilversum will undertake the construction

The support is encased in a metallic cover with double walls, resting on the base plate; the interstice is filled with a bad conductor of heat. A receiver is not needed. The time of an observation being about thirty-five minutes, it is not necessary to operate in a vacuum, which would cause a great complication. In the cover are three windows one for each of the two lenses and one for reading the thermometer and the hygrometer.

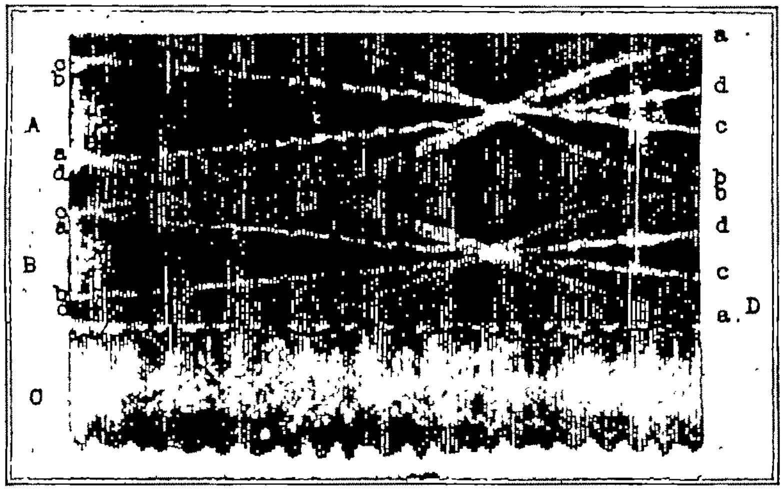

Fig 2.—November 10, Mediterranean Sea, submerged. Curves as on November 2. Undamped pendulum D′ absent.

The whole is placed in the suspension apparatus, the plane of oscillation of the pendulums perpendicular to the suspension axis. The latter must be parallel to the keel of the vessel; in this way the effect of the rolling is neutralised. Originally the apparatus was suspended from pivots, but as the friction caused sudden jerks, these were replaced during the stay at Sevilla by knives, which proved most satisfactory.

The recording apparatus contains two compartments: the small light box and the larger film box.

Behind the light box is placed a Wolfram arc-lamp; the rays of this enter the box through a hole in the back. In the front wall is the small horizontal light-slit, 0·2 mm. wide and 5·0 mm. long, through which the rays leave the box. The interior contains the apparatus for the electromagnetic movement of two shutters, governed by a pair of chronometers, each of which every half second prevents for a moment the light-rays from passing the slit.

The film box contains two vertical cylinders, one bearing the film, which by a clockwork is gradually wound round the other. By the displacement of a lever the velocity with which the film moves can be made 1·0 or 0·33 mm. per second; the first is used at the beginning and the end of the observations, the latter in the intermediate time. Between the cylinders the film moves past a vertical slit in the front wall of the box, 9 mm. wide and 12 cm. high; through this pass the rays coming from the support. The lenses form images of the light-slit on the film, but by a cylindrical lens placed before the recording-slit they are reduced to points. The distance between the optical centres of the lenses is the same as that between the light-slit and the recording-slit. As both slits and both lenses are placed symmetrically with regard to the suspension axis, the place of an image of the light-slit on the film is not changed by the relative movements of the free hanging support and the steady recording apparatus which are caused by the rolling of the vessel.

By the movement of the film the bundles of rays describe the different curves, which, owing to the periodical movements of the shutters, show small gaps that indicate the time elapsed.

The distance between the support and the recording apparatus is 1·03 metre; a tube of blackened cardboard joins the second lens and the vertical slit, and prevents undesired light striking the film.

The two chronometers, constructed by Nardin at Locle, Switzerland, are excellent timekeepers; the irregularities of the daily rate do not exceed 0·1 sec. One, giving sidereal time, has been in use since 1903, the other, giving mean time, is new. It was judged useful to have two chronometers for the purpose of checking each other.

It may be said that in practice the apparatus has surpassed our expectations. The curves recorded on the film are perfectly clear and distinct; their appearance is wholly different from that shown by the films obtained in 1923. This may appear from the accompanying specimens (Figs. 1 and 2) when compared with those given in the *Geographical Journal* for June 1925. The amplitudes of the hypothetical pendulums are entirely regular, which proves that the influence of the horizontal accelerations is wholly eliminated. Letting alone the slow decrease caused by the damping, the amplitudes do not vary more than 0·1 mm., that is 2 to 3 per cent. of the whole amplitude. The vertical accelerations are only perceptible in the track of the half-second gaps, which show slight fluctuations, by tracing a straight line through a number of them the influence is easily eliminated.

Sliding of the pendulums is only to be feared in peculiar circumstances. Thanks to the suspension apparatus, the rolling has no influence, but when the pitching exceeds a few degrees, sliding is noticeable, and the images may even altogether disappear from the film. By the use of the horizontal rudder the pitching of a submerged submarine can generally be greatly reduced, if necessary, after submerging to a greater depth.

Observations with the suspending apparatus hanging free or fastened, executed in quiet water, proved that there is no systematic influence caused by this apparatus.

The advantages of the new apparatus over the old one may be summarised as follows:

1. The exertion required from the observer is a great deal less; he is not compelled during the observations to keep the body in a cramped posture under a black cloth, such as covered the old apparatus.

2. The measurement of the films is very easy, thanks to the clearness and regularity of the recorded curves.

3. The computations are simplified; as the films directly give the movement of the hypothetical pendulums, these have not to be derived by computation from the curves for each separate pendulum.

4. The accuracy of the observations is greater; it is not inferior to that of observations on land.

5. The apparatus may still be used in circumstances where the old one would be useless.

As to the accuracy of the results, it may be remarked that two circumstances unconnected with the apparatus make it somewhat less than that obtainable on land. The first is the varying rate of the chronometers, which may differ during the observations from the mean value, deduced from the time-signals. If scientific radio time-signals of very high precision could be obtained every hour, this would meet the difficulty. The influence is lessened by the use of two chronometers

The second circumstance is the displacement of the vessel during the observations by the sea currents and the resulting contribution to the Eötvös effect. This cannot be determined with accuracy and an average value must be used. I think it improbable that this difficulty will be easily removed.

On board, the apparatus was placed in the central compartment, near the metacentrum, between the two periscopes, one of which was lifted to enable the light-rays to pass

At the beginning of an observation, the first and the third pendulum were set in motion with the desired amplitude. The middle pendulum, hanging free, began to oscillate through the horizontal accelerations caused by the movement of the vessel

The depth of the sea was found by applying the echo method by means of the underwater clock-signals. The lapse of time between the giving of the signal and the perception of the echo was determined by a stop-watch

The time-signals used to determine the rates of the chronometers were generally those of the Eiffel Tower, Bordeaux or Nauen. The relative rate of the chronometers during the observations could be deduced with very great accuracy from the half-second gaps on the films. So far as the computations have been executed, they agree fairly well with the mean relative rates deduced from the time-signals.

During the voyage the following observations were made:

October 17. Mouth of the Channel, near the French coast.
„ 18. Bay of Biscay, not far from the Spanish coast.
„ 26. Sevilla, on the Guadalquivir.
„ 28, 29, 30. Mediterranean Sea, between Gibraltar and Tunis.
November 2. Harbour of Tunis.
„ 8, 9, 10. Mediterranean Sea, between Malta and Alexandria.
„ 12. Harbour of Alexandria.

Some of the observations have been provisionally computed; the results for the harbours of Tunis and Alexandria differ respectively by 0·001 and 0·007 cm./sec.$^{-2}$ from the values obtained in 1923.

The weather was generally very fine and the sea smooth; but on November 27, after the vessel left the harbour of Tunis, a heavy gale was blowing, which prevented the making of observations. The small number of observations in the Atlantic Ocean must be imputed to the circumstance that the time fixed for the track from Helder to Sevilla allowed but small delay. The observations in the Mediterranean Sea constitute a valuable complement to that executed in 1923.

November 26, on board the mail-steamer *Koningin der Nederlanden*, between Crete and Sicily, Dr. Vening Meinesz made a series of observations. The sea was very smooth and the movements of the ship slight The apparatus was placed in a state-room; practical difficulties prevented the use of the suspension apparatus. Some of the observations had to be repeated because of the sliding of the pendulums. The films show the influence of the vibrations caused by the engines, but the amplitudes are very regular. The weather during the rest of the voyage prevented further experiments being made, but it appears from the results that in favourable circumstances it is possible to use the apparatus on board a mail-steamer.

I think that Dr. Vening Meinesz may be heartily congratulated on the success he has achieved with his apparatus. The Geodetic Committee cherishes a strong hope that he will be enabled in the course of 1926 to use it on a second voyage to Java, but this time through the Panama Canal, in this manner concluding a series of determinations of gravity at sea all around the world.

J. J. A. MULLER.

Life in the Bed of the Sea.

IN recent years many attempts have been made to obtain more definite information than the older naturalists had about the composition and the *constitution* of the collections of animals living in the bed especially of the European shallow seas. It was known in a vague way that certain animals were to be found, for example, in a muddy and others in a sandy bottom at certain depths; hence the challenge to modern naturalists to clarify the condition of our knowledge.

The first serious attempt was made by Allen on the grounds off Plymouth, and it was proved clearly that certain forms were definitely associated in that locality with a certain type of bottom which was defined in terms of the percentage composition *in situ* of the particles composing the ground soil. Later, Petersen, employing an approximately accurate instrument, the grab, for taking a definite area of the sea-bottom, obtained figures which showed which animals were really dominant and characteristic in the different areas examined, but that worker failed to follow up Allen's precise work on the physical composition of the soil, and therefore failed to obtain critical information on the problem attacked. Other workers—notably Ford, who attempted to combine the methods of Allen and Petersen—followed, and have in the main always found communities of animals, but communities also in the main in their own particular locality of silty, muddy, sandy, gravelly or stony soil.

It has remained, however, for Davis in a recent publication[1] to combine to some extent the methods of the two chief investigators. Petersen had found different groups of animals living together in different localities and suggested that such animals lived in *communities*, which, however, might vary in different geographical but equivalent localities by the dropping out or addition of certain members. The later worker went further than this and tried to predict the 'communities' which might be expected to occur in (quantitatively) unknown faunas off the European coast.

---

[1] Ministry of Agriculture and Fisheries Fishery Investigations, Series 2, Vol. 8, No. 4, 1925: "Quantitative Studies on the Fauna of the Sea Bottom" No 2: "Results of the Investigations in the Southern North Sea, 1921–24." By F. M. Davis Pp. 50 (London · H.M. Stationery Office, 1925) 5s. net.

By his use of the term 'community' Petersen seems to imply more than Hjort does, for example, in referring to 'societies' or communities of plankton forms in the different hydrographical regions of the Atlantic, or than botanists do in referring to ecological groups of plants, and by his relative neglect of soil analysis gives more importance to the mere association of animals than to the relation of the animals to the nature of the soil. In this attitude Petersen has in part followed Mobius, who long ago (1877) stated that the animals living on an oyster bed form a community, and goes on to say that "Science possesses, as yet, no word by which such a community of living beings may be designated . . . where the sum of species and individuals, being mutually limited and selected under the average external conditions of life, have, by means of transmission, continued in possession of a certain definite territory. I propose the word *Biocœnosis* (from *bios*, life, and *koinoein*, to have something in common) for such a community."

Obviously all these are the beginnings of attempts in marine zoœcology or *zoocœnosis*; and we are witnessing the early stages in the evolution of a nomenclature and, indeed, of method. Davis adopts, but unfortunately, we think, in a modified way, the Allen-Borley method of soil analysis, and pays insufficient attention to the hydrographical and topographical variants, which both Petersen and Borley noted. Thus in no case are all the correlated observations to date marshalled in such a way as to indicate an enduring natural classification of such associations or groups as do undoubtedly occur, although Petersen's broad method of treatment alone has certainly carried the problem beyond its initial stages. In his paper, Davis gives a remarkable table showing soil-analyses correlated with the animals inhabiting particular soils and clearly shows that a large number of animals prefer a particular soil in the North Sea, though some are more catholic in habitat. The author concludes that animal associations were found, but that in detail those groups (communities) which Petersen found are not homogeneous in nature when regarded in relation to the soil analyses, nor strictly comparable with one another in the areas investigated.

We hold, however, that there is not enough information available for the latter part of the conclusion, since (1) Petersen gives no analysis of soils to define his communities, (2) the fauna in relation to known soils has not been adequately investigated at stations linking Petersen's scene of work with the North Sea stations, (3) Davis has himself grouped together animals only in relation to soils without consideration of other biological factors—despite Borley's warning—and (4) what is more important, the biological significance of the soil and medium for the animals inhabiting them has scarcely yet been considered, and a close study of individual species will be required to give the information needed on this point.

The trend of modern work is indeed to delimit and to come to grips with the problem of the relation of any animal to its habitat. The essence of the work on marine animal communities is the provision of a complete description of the factors of the habitat and the inter-relationships of the members, and the results should be stated so as to be capable of comparison or contrast with one another in all parts of the world. J. H. O.

Applied Psychology.

Prof. J. McKeen Cattell, the retiring president of the American Association for the Advancement of Science, gave in his address at Kansas City on "Some Psychological Experiments," a portion of which was published in Nature of January 16, an illuminating account of the development of the experimental study of individual differences. Starting with a description of the measurement of a simple sense reaction time, he proceeded to show, step by step, how the same type of objective measurement can be used in such a complicated action as the selection of a career.

Although no striking new experiments were described, Prof. Cattell's account of the recent applications of psychology was both original and stimulating. "Daily, weekly and seasonal curves," he says; "the optimum periods for definite tasks and for a day's work; industrial fatigue; temperature, ventilation and humidity; the most desirable sexual relations, food, amount and distribution of sleep; rest, play and physical exercise, the use and misuse of emotional excitement and of drugs as sedatives and stimuli: these have been the subjects of many investigations. . . ."

An interesting point discussed by Prof. Cattell is the variation of the curve of ease of learning with age. It is well known that a young child can learn to pronounce a foreign language more easily than can his father and mother. Three years is found to be the optimum age for acquiring pronunciation, and after the age of twelve years it can but rarely be learnt correctly. In the same way other abilities—both physical and mental—have their optimum learning curve at various ages. It is an important task for the educational psychologist to examine the practice curves of the ordinary school subjects at different age levels, so that he can suggest at what stage they should be commenced. Mathematical relations, Prof. Cattell finds, are generally taught a couple of years before the child's age allows him to respond to them with the least effort.

Reference is made to the work that is being done in England by the National Institute of Industrial Psychology to reduce industrial fatigue. Psychologists have found that by arranging for suitable alternative periods of rest and exercise, and by supplying training in the use of the most physiologically economical movements, it is possible to increase the output of the worker—be he miner, mill-hand, or typist—and simultaneously reduce his fatigue. Prof. Cattell outlines the enormous economic importance of this work and describes how in America a Psychological Corporation has been formed to advance this new science, to allow of research, and to protect the interest of psychologists. "The Father of American Psychology," as Prof. Cattell is well named, is the president of this Corporation, and its establishment has already been amply justified. W. J. G. S.

University and Educational Intelligence.

Birmingham.—Dr. Daniel Hanson, principal assistant in the Metallurgy Department of the National Physical Laboratory, Teddington, has been appointed to the Feeney chair of metallurgy, which will be vacated by Prof. T. Turner at the end of the current session.

Mr. J. Armitage Robertson has been appointed assistant lecturer in zoology.

London.—The following doctorates have been conferred: *D.Sc.* (*Chemistry*): Mr. H. T. S. Britton (King's College and Imperial College—Royal College of Science), for a thesis entitled "Part I. Some Electrometric Studies of Reactions, with special reference to the Precipitation of Basic Salts; Part II Some Studies of Salts of Rarer Metals"; Mr. H. D. K. Drew (Birkbeck College), for a thesis entitled "Heterocyclic Systems containing Tellurium in the Ring"; and Mr M. A. Matthews (East London College and the Sir John Cass Technical Institute), for a thesis entitled "The Reactions of the meso-Hydroxy Anthrones and their Bearing on the Mechanism of certain Reactions"; *D.Sc.* (*Statistics*): Mr. E. S Pearson (University College), for a thesis entitled "Bayes' Theorem examined in the Light of Experimental Sampling"; *D Sc.* (*Geology*): Mr. George Slater, for a thesis entitled "Glacial Tectonics as reflected in Disturbed Drift Deposits," and other papers, *D Sc.* (*Horticulture*): Mr. H. R. Briton-Jones, for a thesis entitled "On the Diseases known as 'Bark Canker' and 'Die-back' in Fruit Trees," and other papers; *D.Sc.* (*Physics*): Mr. L. F. Richardson, for a thesis entitled "Collected Works on Meteorology, Differential Equations, etc."

DR. H. R. BRITON-JONES, lecturer in mycology in the Department of Agriculture of the University of Bristol, has been appointed professor of mycology to the Imperial College of Tropical Agriculture, Trinidad.

MR. FRANK BALFOUR-BROWNE, formerly lecturer in zoology (entomology) in the University of Cambridge, has been appointed professor of entomology in the Imperial College of Science and Technology, South Kensington, in succession to the late Prof. H. Maxwell Lefroy.

APPLICATIONS are invited for two scholarships in connexion with the Manchester Royal Infirmary, namely, the Dickinson research travelling scholarship in medicine, value 300*l* for one year, and the Dickinson pathology scholarship, value 75*l* for one year. Particulars are obtainable from the Secretary to the Trustees, The Royal Infirmary, Manchester. The latest date for the receipt of applications for the scholarships is May 1.

A CENSUS of graduate research students in chemistry in the United States in 1925 shows that of 1763 such students in 121 universities, colleges, schools of engineering and agriculture, medical schools, and schools of pharmacy, 544 were engaged on work in the physico-chemical group of subjects: general, colloid, catalysis, subatomic, electro-chemistry, and photo-chemistry. Organic chemistry comes next with 430 students of whom 44 per cent. were working on the aliphatic series. The remainder are classified under the groups, medicine (333), agricultural, industrial, and engineering chemistry (237), inorganic chemistry (86), analytical and metallurgical (72), sanitary and food (61).

IN connexion with the celebration of the fiftieth anniversary of the Johns Hopkins University, it is proposed to establish a Brooks Research Fund in memory of the late Prof. William Keith Brooks. The income of this Fund is to be used to give to some advanced student in zoology or in botany aid in carrying out his work in direct contact with Nature, as at a tropical marine laboratory, or under other stimulating conditions of environment for growth and widening of experiences. The hope would be that from time to time some man thoroughly devoted to zoology or to botany might receive in this way needed aid at a critical point in his career. An offer of five hundred dollars has been received if a further ten thousand is raised. The Fund will be distinct from that now being raised to celebrate the jubilee of Johns Hopkins. Prof. E. A. Andrews, Johns Hopkins University, is chairman of the appeal committee.

"WHAT every woman's college course ought to include" is a question which has been much discussed of late by the Faculty of Barnard College, Columbia University. The conclusions arrived at as a result of these discussions are described in an article by the Dean of the College, Virginia C. Gildersleeve, in the December number of *School Life*. While recognising that in many fields of work it is almost impossible to say that one subject is for all students more valuable than another and a wide range of choice must be permitted, the College prescribes for all the mastery of certain fundamental tools useful for successful work in any field. These are: "A command of written and spoken English, the ability to read at sight with ease at least one foreign language, a healthy body, and a knowledge of hygiene." To ensure the acquisition of these tools, courses in English composition, spoken English (chiefly for remedying defects of the voice), personal hygiene, and human biology are made compulsory—the three first-mentioned being taken during the first of the four years of college life. All students are also obliged to take, during their four years, appropriate physical exercise. As regards the selection of the remainder of the curriculum, two general rules are laid down. On one hand every candidate for a degree must pursue in some one subject a course, carefully planned and supervised by the department concerned, on lines designed to ensure a fairly thorough knowledge of it. On the other hand, in order to avoid too much concentration, every student is required to reach a certain minimum standard in at least one subject chosen from each of the three groups—languages, literatures, and fine arts; mathematics and natural sciences (including some laboratory work); and social sciences.

A REVIEW of Education in India in 1923-24 by the acting Educational Commissioner, which the Government of India has recently published, shows that in the field of higher education the year was in several respects one of disillusion and reaction. In the University of Allahabad, for example, the new constitution was found to keep the minds of the teachers so engaged in the technicalities of meetings of university bodies that they had insufficient time left for teaching duties. In Bengal a widespread dissatisfaction with the existing university system found expression in a reaction against literary education and a preference for science courses. From Assam came reports that graduates and undergraduates seek employment in vain and create discontent with the system which has brought them to such a plight. The University of the Punjab was reported to be "becoming more and more on the major side of its activities an examining body." The policy of separating the intermediate classes from the university course of study has been found in the United Provinces, where it was tentatively adopted, to be unworkable for the present in the colleges which prepare degree candidates. In Bombay the school-leaving certificate examination does not altogether fulfil the hopes with which it was instituted, and it was decided that the University should resume the conduct of its matriculation examination. The Dacca Vocational Education Committee presented a report in which doubt is thrown on the belief of the Calcutta University Commission that at the intermediate stage vocational education can be so combined with general education as to produce a worker competent to earn his living with the training which he has undergone at the close of that stage. There was also disillusion of a beneficent kind on the part of some political enthusiasts and the effect of the non-co-operation movement on attendance in schools became negligible. The University of the Punjab embarked on a new venture in the opening of its first science laboratory—that of chemistry.

Contemporary Birthdays.

April 11, 1862.	Prof. W. Wallace Campbell, For Mem.R.S.
April 11, 1863.	Mr. Henry Balfour, F.R.S.
April 11, 1890.	Dr. Eric K. Rideal.
April 12, 1851.	Mr. Edward Walter Maunder.
April 14, 1867.	Prof. J. C. M'Lennan, F.R.S.

Prof. W. W. CAMPBELL, the distinguished director of the Lick Observatory, Mount Hamilton, California, and president (since 1923) of the University of California, was born at Hancock Co., Ohio. The development of astronomical knowledge owes much indeed to him during the past thirty-five years, not only for practical issues, but also for valuable contributions to the journals recording theoretical progress in the science of astronomy. He has had charge of many eclipse expeditions, and those who were privileged to act with him have testified to his enthusiasm, powers of organisation, and resourcefulness. Prof Campbell was among those who were successful in adopting the method of employing a moving photographic plate to record the succession of phenomena during a solar eclipse. The Royal Astronomical Society awarded him its gold medal in 1906 for his spectroscopic researches on stellar objects, and work respecting stellar motions in the line of sight. The Paris Academy of Sciences allotted Prof. Campbell the Lalande medal in 1903, and the Janssen medal in 1910, for researches and discoveries in stellar spectroscopy.

Mr. HENRY BALFOUR was educated at Charterhouse and Trinity College, Oxford. Since 1891 he has been curator of the extensive ethnological and archæological collections acquired by the late General Pitt Rivers, F.R.S., and presented by him to the University of Oxford in 1884 Huxley medallist of the Royal Anthropological Institute, and a past president of the Folk-lore Society, Mr. Balfour is the author of many noteworthy memoirs.

Dr. E K. RIDEAL is an old pupil of Oundle; from thence he graduated at Trinity Hall, Cambridge. He is Owen Jones lecturer in physical chemistry in the University of Cambridge. For a year (1919–20) Dr. Rideal was visiting professor of physical chemistry in the University of Illinois, U.S.A.

Mr. E. W. MAUNDER, astronomer, entered the service of the Royal Observatory, Greenwich, as an assistant in 1873, and from that date until 1913 he was Superintendent of the Solar Department. Mr Maunder was educated at University College School, London, and King's College. He has taken part in many eclipse expeditions Author of a number of useful works on practical and popular astronomy, he has in several of these had the happy advantage of Mrs. Maunder's collaboration. He founded the British Astronomical Association in 1890.

Prof. J. C M'LENNAN, Director of the Physical Laboratory in the University of Toronto, though born at Ontario, is of Scottish descent. He received his education at the Universities of Toronto and Cambridge. His attachment to the former began in 1892, and has never been severed. Prof. M'Lennan was president of the Royal Society of Canada, 1924–25. In 1923 he was president of Section A (Mathematics and Physics) at the Liverpool meeting of the British Association; the subject of his discourse was, "On the Origin of Spectra." The Royal Society of Arts allotted him a medal in 1919, for his paper "Science and Industry in Canada." He is D Sc., Manchester and Liverpool.

Societies and Academies.

LONDON.

Royal Microscopical Society, February 17.—**A. Piney**: The principles of hæmatological differentiation. An attempt to classify the normal leucocytes of human blood on purely morphological grounds. The characters of the nuclei must be regarded as the determining feature, particularly the distribution of the two forms of chromatin Cells with sharp distinction of the chromatin into two types were derived from the bone marrow (myeloid cells), while those with incomplete separation of the two substances in the nucleus were of lymphatic origin. The technical details of preparing the films were discussed.

Royal Microscopical Society (Industrial Applications Section), February 24.—**C. A. Klein**: The application of the microscope to the examination of pigments and paints. More precise information is required as to the size of pigment particles in view of the important relationship known to exist between particle size and the subsequent behaviour of paints, in respect to ease of application and also wearing properties The methods of sieving and subsidence frequently used to indicate the fineness of division of pigments have limitations, and microscopical examination is recommended after grading of the material by elutriation, in order to obtain fields of more even-sized particles. The removal of even small proportions of over-sized particles in paint materials is an expensive process. Many problems in connexion with the behaviour of paint films on drying and subsequent exposure could be solved by the proper application of microscopical methods as in the United States of America, where they have been applied to a considerable extent.

Royal Anthropological Institute, March 2.—**Mrs. Janet B Montgomery McGovern**: The head-hunters of Formosa. The Chinese-Formosans of the towns do not differ materially from the Chinese of the mother country; it is among the pseudo-aboriginals of the almost inaccessible mountain ranges that curious customs are observed. Of these tribes the most interesting are the Taiyal, the head-hunting tattooed tribe of the northernmost mountains. A feature of their culture is the government of the tribe by women. Their power is both spiritual and temporal. The chieftainess of each sub-tribe is also the priestess of that sub-tribe. She is assisted by other priestesses, mostly widows. They officiate at marriage and funeral ceremonies, and act as physicians in case of illness, effecting some marvellous cures. The chief priestess also performs the ceremonial tattooing. All the children have their foreheads tattooed in a series of horizontal marks at the age of five years. At marriage, elaborate markings are tattooed on the cheeks of the bride, and on attainment of the rank of priestess further elaborate markings are added. The warriors are also tattooed by the priestess. One function of the priestess is the ceremonial kindling of new fire once a year. From this all fires are re-lighted The priestess also decides when head-hunting expeditions are to be carried out, and in what direction No warrior may marry unless he has at least one head to his credit For each head that is taken, a horizontal mark is tattooed on the chin An essential part of the marriage ceremony is that bride and groom should drink millet wine from a cup made of a skull taken by the latter. A communal system prevails among the Taiyal, the millet, the principal food of the people, being distributed by the high priestess from the communal granaries. A very high standard of personal morality exists among them, and untruths, theft, and unchastity are almost unknown where the people have not come into contact with civilisation.

March 16.—G. Landtman: Some agricultural rites of the Kiwai Papuans. The gardening of the Kiwais, like all their occupations, is interwoven with all kinds of observances purporting to promote the work. When clearing timbered bush the people avoid felling certain large trees which are thought to be inhabited by the *étengena*, a group of sylvan beings. These appear by day as snakes or birds, at night in human form, and are guardians of the plantations. The people give them part of the first-fruits and invoke them in the *karéa*-rite, sprinkling of *gámoda* (*káva*) in the direction of the garden. Most of the fertility rites are first performed in the garden by an old man and an old woman, whose example is followed by the rest of the people. In several of the rites the sexual act plays a part, and one of the principal "medicines" is secretion from the female genitalia, for sago palms the male semen. The people also resort to various methods for depriving an enemy of his luck in gardening, or for summoning pigs to destroy his crop. The old couple generally lead the way in every stage of garden work with their preparatory rites. Each of the principal garden plants is attended by observances of its own. Bullroarers are particularly used for yams. The first few yam stalks are usually tied up with strings which have been employed for cat's cradles "Skipping-rope" is a game which causes the yam roots to grow large. Certain rites at the first cropping of a garden purport to make the food last a long time and prevent the people from being taken ill when eating it. A series of rites referring to the banana gardens are performed by a number of small boys, each with a little "play-wife." These small couples bear resemblance to the various descriptions of "May-brides," etc. The principal feature of the *gaera*, the great agricultural ceremony, is a tree erected on the festal ground with much solemnity, overhung with garden produce and beautifully decorated. A long serial song is sung during the ceremony, describing a journey from Adiri, the land of the dead, in an easterly direction right through the part of the country known to the Kiwais. One cannot forbear recognising one of the many instances of the fertility tree or the tree of life.

Mineralogical Society, March 16.—A. F. Hallimond: On molecular volume relations in the mica group. The 'observed' molecular volume is obtained from the density and silica-percentage, on the assumption that the mica molecule contains the same number of silicon atoms for all members of the group. It is shown that the molecular volumes so obtained are of similar dimensions throughout, but that each of the non-miscible sections, muscovite, lepidolite, etc., has a distinctive molecular volume, in agreement with the chemical classification proposed in earlier papers. The volume is an additive property, and can be expressed as the sum of the volumes of the oxides present. The corresponding absolute molecular volumes for the oxides are in general agreement with those derived from X-ray measurements. Micas deficient in potash do not show a corresponding diminution of volume. Titanium is usually present as TiO_2, but two titanium-rich biotites only give normal molecular volumes when represented as compounds of Ti_2O_3.—E. D. Mountain: (1) Smithsonite from the Rhodesia Broken Hill Mines. Colourless crystals 7 mm. in size, in the British Museum (Natural History), are of the form f(111), striated parallel to longer diagonal; cleavage angle $rr' = 72° 21'$; $H = 4 - 4\frac{1}{2}$; $G = 4·398$; contains 97·34 per cent. $ZnCO_3$. Refractive indices measured on oriented prisms gave for Na-light $\epsilon = 1·6212$, $\omega = 1·8485$. (2) The identity of the Cobija and Lampa meteoric stones. A complete quantitative analysis of Cobija and a partial analysis of Lampa confirm Dr. Prior's suggestion of their identity; $f = 14$, $n = 10\frac{1}{2}$, $m = 5$ (Prior's nomenclature); specific gravity, 3·58. Further evidence suggests that they are two stones of the Cobija fall.—C. E. Tilley: On garnet in pelitic contact zones. In the normal pelitic contact zone, garnet is inconstant in its occurrence, and from many aureoles is entirely absent. The instability of almandine in normal thermal metamorphism is attested by the destruction of this mineral when crystalline schists containing it are involved in the aureoles of the Caledonian granites of Scotland. Aureoles especially conspicuous for the presence of garnet are those of New Galloway, Co. Wicklow, and Skiddaw. Analyses of garnets from these show considerable spessartine percentages, varying from forty to fourteen. The occurrence of garnet in pelitic contact zones (stress zones excluded) appears to be conditioned by the presence of a considerable MnO content, promoting the formation of spessartine bearing types. Almandine proper is characteristically a stress or high-pressure mineral; the physical conditions for its formation are not realised in normal thermal aureoles.

Royal Meteorological Society, March 17.—Sydney Chapman: Some recent advances in atmospheric physics (Symons Memorial lecture). The existence of a strongly ionised layer in the upper atmosphere, required by theories of the daily variations of the earth's magnetism, and also required to explain the long-distance transmission of wireless waves, has recently been strikingly demonstrated by observations of high-angle reflection of short-wave wireless signals at night The wireless and magnetic data for the ionised layer are in fair qualitative and also quantitative accord where they overlap. It appears possible to explain the production of the ionisation by ultra-violet radiation absorbed in the atmosphere by day, certain quantitative difficulties proposed by Swann being found invalid. Additional ionisation occurs, by night as well as by day, in higher latitudes, in association with auroræ. The nature of the ionising agent in this case is somewhat obscure, but a stream of charged corpuscles of opposite signs, but with a slight residual charge, seems the most likely hypothesis. The auroral spectrum suggests that nitrogen is the principal ionised gas in the auroral regions.

Royal Microscopical Society, March 17.—Mohammed Ali: Studies on *B. ægypticus*, Pt. I. The appearance and structure of colonies of this organism upon artificial media and its morphological characters were described. Variations in the H-ion concentration of the medium transforms the minute rod of 1 μ into a filament often thirty times that length, which latter could be restored at will to the type form, thus demonstrating that heritable tendencies are not involved. In this respect *B. ægypticus* behaves in a precisely comparable manner to *B. influenzæ* (Pfeiffer). There is a lack of morphological, tinctorial and cultural difference between these two members of the hæmophilic group of bacilli; the only differentiating point so far observed has been the longer vitality upon artificial media of *B. influenzæ*.

Edinburgh.

Royal Society, March 8 —**N. B. Eales**: The anatomy of the head of a fœtal African elephant. The muscles, blood-vessels, nerves and skeleton are described. Despite its youth, the skull possesses the features of a modern elephant, and the flattening of the facial region at the root of the proboscis has already taken place. No traces of the first premolar or of the lower incisor teeth are present. All the teeth of a young elephant are represented and no others. The fœtal mandible exhibits the *longirostris* condition and is turned downward at the symphysis. Its vertical measurement is relatively shorter and its horizontal measurement relatively greater than in the adult. The shape resembles that of the fœtal elephant's ancestors rather than that of its own parents.—**C. M. Yonge**: The digestive diverticula in the lamellibranchs. The so-called liver or hepatopancreas of the lamellibranchs consists of a great number of ramifying blind tubes, the epithelium of which is composed of one kind of cell only. There is no evidence that the cells secrete or perform any of the functions of a liver or a pancreas; the whole structure is an organ of absorption and intercellular digestion, small particles being directly ingested and acted upon by digestive enzymes within the cells. The only extracellular enzymes in the gut of lamellibranchs are those elaborated in the crystalline style.—**W. Peddie**: Present problems in colour vision: the laws of visual fatigue, and of resultant sensation. The paper deals specially with the form of the relation which expresses the threshold value, that is, the least perceptible value, of an external stimulus, in terms of the external stimulus itself. This expression is then generalised so as to take account of interrelation of effects, and of the influence of any given fatiguing light to which the eye may have been previously exposed This generalisation furnishes an explanation of the peculiar effect of strong precedent fatigue upon the sensitiveness of the eye to spectrum colours, which has been investigated in detail by Prof Frank Allen.—**F. A. E. Crew**: On fertility in the domestic fowl. Fertile eggs are to be expected about 48 hours after the introduction of the male into a pen of virginal laying females; the onset of fertility varies slightly in different matings. The maximum fertility is attained by the end of the first week. Although fertile eggs are laid so long as 21 days after removal of the male, yet should the male be replaced by another, then the influence of the previous sire is removed by the end of the first week. This competitive action of the sperm is probably to be explained in terms of their relative staleness.—**H. W. Turnbull**: The invariant theory of forms in six variables relating to the line complex. A symbolic algebraic basis is given for the treatment of quaternary complex forms which occur in line geometry as forms in six variables, as suggested by Klein. The most general case including point, line and plane co-ordinates is considered. The transformation is reversible.—**Pierre Humbert**: Some hyperspace harmonic analysis problems introducing extensions of Mathieu's equation. Mathieu's differential equation, specially studied by Prof. E. T. Whittaker, is of great importance in harmonic analysis; two other equations, similar to it, are here connected with some new problems in four-dimensional space.—**W. Saddler**: A geometry associated with the double binary (2·2) form. The vanishing of the form as the incidence condition of a point on one conic with a tangent to a second, both represented parametrically, is treated. Canonical forms and the covariants are readily obtained and interpreted, while applications, using two (2·2) forms, are given to the geometry of three conics.

Paris.

Academy of Sciences, February 15 —**Paul Appell**: A principle of statics.—**V. Grignard** and **J. Savard**: The existence of isopulegone in the natural state. The isolation of the α- (iso) pulegones and β- (ordinary) pulegone and their enols in the pure state. The separation is based on the fact that pulegone combines with sodium bisulphite, whilst isopulegone is not attacked by this reagent.—**G. Friedel**: Concerning fatty acids and smectic bodies.—**Axel Egnell**: A property of curvature of certain Riemann spaces.—**Charles Jordan**: The inversion of the theorem of Bernoulli.—**Rod. Fueter**: Improperly discontinuous groups.—**Michel Petrovitch**: Definite integrals bearing on the generalised series of Lambert.— — **Mandelbrojt**: The effective determination of the singular points of an analytical function given by its development in series of powers —**J. Sudria**: A theorem of the vectorial calculus.—**R. Swyngedauw**: An experimental method for the study of the working of belts.—**M. Girault**: The intrinsic equations of the plane parallel motion of incompressible fluids in a permanent régime.—**Y. Rocard**: Conditions at the surface in problems of aerodynamics furnished by the kinetic theory of gases.—**V. Bjerknes**: The temperature of sunspots. The assumption of vortex movements can explain the existence of parts of the sun's surface either locally cooled or heated.—**H. Pélabon**: The mechanism of detection (in wireless telegraphy).—**Léon Bloch**, **Eugène Bloch**, and **Georges Déjardin**: A second spark spectrum of neon. A description of a new spark spectrum of the second order, the lines of which are wholly situated in the ultra-violet.—**Georges Déjardin**: The excitation of the second spectrum of neon by electronic shock.—**E. Darmois**: The mutarotation of mixtures of molybdates and ethyl malate. The probable constitution of the molybdomalic derivatives.—**Albert Nodon**: An electrometer designed for the study of weak radioactive manifestations. The instrument described has a small electrostatic capacity, and indicates variations of 2 volts —**J. d'Espine**: The slowing down of the β-rays by matter —**Max Morand**: The direct determination of the relative proportion of the isotopes of lithium. Making use of an improved apparatus for the production of positive rays, the currents transported by the positive rays of the two isotopes of lithium have been measured, receiving the isotopes on two separated plates, each connected with a galvanometer. The numbers obtained give a ratio of intensity between 14 and 15, corresponding to an atomic weight of between 6·93 and 6·94. The chemical determination of the atomic weight, 6·935, is in good agreement.— — **Herrera**: New experiments simulating living organisms.—**Victor Lombard**: The permeability of nickel to hydrogen. The influence of pressure. The permeability of nickel to hydrogen, within the limits of the experiments described, is proportional to a^{-h}, where h is the thickness of the nickel plate. It is an exponential function of the temperature, and varies proportionally to the square root of the pressure of the gas.—**J. Laissus**: The cementation of ferrous alloys by tungsten.—**R. Cazaud**: Researches on the auto-magnetisation of steels by torsion. The study of the auto-magnetisation of steels by torsion gives a rapid method of identification, capable of furnishing indications of their composition and thermal treatment.—**B. Bogitch**: The composition of copper mattes.—**P. Billon**: The reduction of oximes by sodium and absolute alcohol. Splitting up the racemic amines thus obtained by means of dextrorotatory tartaric acid.—Louis **Longchambon**: The tartaric acids. Study of the preparation and properties of antitartaric acid (inactive).—André **Duparque**: The microscopic structure of coals.—Mlle. Yvonne **Wahl**: Tectonic and stratigraphic observations in the region of the lake of Allos (Basses-Alpes).—J. **Savornin**: The discovery of native gold at Djebel Mekam, near Berguent (Eastern Morocco).—Maxime **Coutin**: A layer of molybdenite in Morocco.—R. **Cerighelli**: The influence of light and temperature on the germination of seeds in the absence of calcium. In the germination of the pea, in the absence of lime, light exerts no influence on the growth of the root and stem, but the temperature has a marked action on each of these organs.—A. **Guilliermond**: The relations of the vacuolar system with the reticular apparatus of Golgi in plants.—Marcel **Brandza**: The influence of heat and of rapid evaporation on calcareous myxomycetes living in full sunlight.—Pierre **Georgévitch**: *Armillaria mellea*, the cause of the drying up of the oak forests of Jugoslavia.—A. **Quidor** and **Marcel A. Hérubel**: The monocular perception of relief by direct observation.—H. **Simonnet** and G. **Tanret**: The action of ergotinine on the uterus of the guinea-pig.—Pierre **Lesne**: A coleopterologic Pliocene fauna in the north of England.—Émile **André** and Mlle. Th. **François**: Contribution to the study of the oils of marine animals. Researches on cachalot and spermaceti oils.—Mme. **Phisalix**: The vaccination of the rabbit against intracerebral inoculation of fixed rabies virus, by subcutaneous inoculation of virus-serum mixtures from the viper, the adder, or the hedgehog, with excess of virus.—**Loubat** and **Dufériè**: The influence of vascular ligatures on experimental gas gangrene.

ROME.

Royal Academy of the Lincei, January 17.—Umberto **Cisotti**: Mechanical actions of a plane current investing two circular profiles separated by a convenient distance.—Secondo **Franchi**: Discoveries of Priabonian foraminifera in the Taveyannaz arenaria, confirming the Eocene age demonstrated for the Annot arenaria in 1916.—Harry **Levy**: Canonical form of the ds^2 for which Riemann's symbols with five indices are annulled.—Alfredo **Rosenblatt**: The case of general collision in the problem of three bodies.—A. **Pontremoli**: New investigations on the accidental double refraction of colloids in motion.—Elena **Freda**: Propagation of stationary electric currents under the action of a magnetic field.—A. **Carrelli**: The compound photo-electric effect.—Giulio **Bemporad**: The principle of the arithmetic mean.—G. R. **Levi** and R. **Haardt**. The catalytic action of metals of the platinum group and their degree of subdivision (1). Measurement of the dimensions of the granules of a number of preparations of platinum black and spongy platinum shows that it is possible to alter the magnitude of these granules by varying the method of preparation. Reduction of cold chloroplatinic acid by means of aluminium yields granules only five times as large as the elementary cell.—P. **Pasquini**: The structure of pecten and its morphological and functional significance in the eye of the bird.

Pontificia Accademia delle Scienze (Nuovi Lincei), February 21.—**Toniolti**: Telluric movement of Amiata at Montalcino.—**Luigioni**: Specific validity of *Anoxia sicula* Motsch, a beetle of the scarab family.—**Gianfranceschi**: The law of distribution of energy in the spectrum of the black body.—**Scatizzi**: A type of derivative of variable index capable of summing its index with another derivative of the first type.—**Silvestri**: Invariable radiophonic receiver.

VIENNA.

Academy of Sciences, January 22.—K. **Hofler**: The iron content and local iron concentration in the cell walls of Desmidaceæ.—A. **Kailan** and J. **Schroth**: The electric conductivity of mixtures of hydrochloric and sulphuric acids with orthophosphoric acids prepared in various ways.—A. **Kailan** and J. **Schroth**: The esterification of malonic acid by hydrochloric acid in glycerin.—R. **Dworzak**: Ester-condensation in relation to the exchange of functional groups under the influence of aluminium ethylate.—B. P. **Wiesner**: The sexual cycle of the rat. (1) The œstrous rhythm and the œstrous cycle; (2) phases of the sexual cycle; (3) castration and extirpation of the suprarenals; (4) periodicity in the secretory function of the ovary and the œstrous rhythm.—O. **Lehmann**: Devastation in the Sandling group in the early autumn, 1920.—L. **Hofmann**: The axonometric theorems of Kruppa and Pohlk in non-Euclidean space. It relates to descriptive geometry and projections and curves of the second degree.—A. M. **Hugetz**: The influence of the alcoholic components on the velocity of saponification of acetic ester.—M. **Skrabal** and M. **Zlatewa**: The velocity of saponification of tetra-acetyl-penta-erytrit.—M. **Glässner**: New Emyden discoveries in the Vienna basin and fossil species of Clemmys in the Mediterranean region.—A. **Kieslinger**: Geology and petrography of the Kor Alps.

MONDAY, April 12.

Royal Irish Academy, at 4.15.

Royal Institution of Great Britain, at 5.—General Meeting.

Society of Engineers (at Geological Society), at 5.30.—H. B. Creswell: An Inquiry into the Ugliness of Engineering Structures.

Institution of Electrical Engineers (Western Centre) (at Exeter), at 6.—R. B. Matthews: Electro-Farming; or the Application of Electricity to Agriculture.

Institution of Structural Engineers (Students' Meeting), at 6.—E. S. Andrews and others: Discussion on Theory *versus* Practice.

Institution of Automobile Engineers (Birmingham Centre) (at Birmingham and Midland Institute), at 7.—G. Rushton: The L.G.O.C. Methods of Omnibus Repair (Lecture).

Institution of Electrical Engineers (Informal Meeting), at 7.—Capt. P. P. Eckersley and others: Discussion on the Linking together of Wireless and Wire Communication Systems.

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—C. Vernier: Some Impressions of Chicago and U.S.A. (Lecture).

Institution of Mechanical Engineers (Graduates' Section, London), at 7.—F. C. Johansen: Some Factors affecting the Speed of Passenger Trains.

Aristotelian Society (at University of London Club), at 8.—Rev. E. Hanson: The Problem of History.

Surveyors' Institution at 8.—Discussion of Paper by H. E. Sherwin, On the Various Statutes which comprise the New Law of Property.

Royal Geographical Society (at Æolian Hall), at 8.30.—H. F. Lambart: The Ascent of Mount Logan.

Society of Chemical Industry (London Section).

TUESDAY, April 13.

Manchester Geological and Mining Society, at 4.

Royal Society of Medicine (Therapeutics and Pharmacology Section) (Annual General Meeting), at 5.

Royal Institution of Great Britain, at 5.15.—Prof. J. Barcroft: Organs of Multiple Function (1): The Salivary Glands.

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—C. M. Hunter: The Oil Fields of the Maracaibo Basin.

Zoological Society of London, at 5.30.—Dr. K. Kuiper: On a Black Variety of the Malay Tapir (*Tapirus indicus*).—B. S. Vinogradov: Some External and Osteological Characters of *Prometheomys schaposchnikowi* Satun (Rodentia).—Dr. P. R. Lowe: On the Callosities of the Ostrich (and other Palæognathæ) in connection with the Inheritance of Acquired Characters.—W. S. Bristowe and G. H. Locket: The Courtship of British Lycosid Spiders and its Probable Significance.—Dr. J. Beattie: On the Ileocæcal Region of the Reptiles.—L. *Tupinambis teguexin*.—J. H. Power: Note on the Tadpoles of *Cassina senegalensis*.

Institution of Civil Engineers, at 6.—J. N. Reeson: The Influence of Electric Welding in the Design and Fabrication of Plant and Structures.

Institute of Marine Engineers, at 6.30.—W. S. Burn: Double-Acting Oil Engines.

Royal Photographic Society of Great Britain (Scientific and Technical Group), at 7.—S. O. Rawling: Thiocarbamide Fog and a Suggested Explanation of Waterhouse Reversal.—A. Montagny: Demonstration of the Hilo and Moutix Apparatus.

Institution of Electrical Engineers (Scottish Section) (at Royal Technical College, Glasgow), at 7.30.—Ordinary and Annual General Meeting.

Institution of Engineers and Shipbuilders in Scotland (at 39 Elmbank Crescent, Glasgow), at 7.30.—A. Healey: Dunlop Tyres and their Uses.

Quekett Microscopical Club, at 7.30.—J. Ramsbottom: Fairy Rings and Allied Growths.

Royal Anthropological Institute, at 8.30.—J. Stuart: The Zulus in Peace and War.

WEDNESDAY, April 14.

Royal Institute of British Architects (at 9 Conduit Street, W.), at 5.—F. Inigo Thomas: Gardens (Lecture).

Institution of Civil Engineers (Informal Meeting), at 6.—G. W. Tripp: The Young Engineer: His Training and Prospects.

Institution of Electrical Engineers (Wireless Section), at 6.—E. H. Shaughnessy: The Rugby Radio Station of the British Post Office.

Radio Society of Great Britain (Informal Meeting) (at Institution of Electrical Engineers), at 6.

Institution of Electrical Engineers (South Midland Centre) (at Birmingham University), at 7.—Discussion on Government Electricity Bill.

Royal Society of Arts, at 8.—Principal R. A. Dawson: Art Training for Industry, and the Royal Society of Art's Competitions.

Society of Chemical Industry (Chemical Engineering Group) (jointly with Institution of Chemical Engineers) (at Burlington House, Piccadilly), at 8.—J. Kwantes: The Beet Sugar Industry.

Liverpool Engineering Society (at 9 The Temple, Liverpool), at 8.—R. Waddell: The Properties and Engineering Uses of Stainless Steel.

Eugenics Education Society (at Royal Society), at 8.30.—G. C. Robson: Observations of the Selective Death-rate in Nature (Lecture).

Institution of Structural Engineers (Lancashire and Cheshire Branch), Annual Meeting.

THURSDAY, April 15.

Linnean Society of London, at 5.—Prof. C. Schroter: The Swiss National Park and Scientific Researches into its Nature (Hooker Lecture).

Royal Institution of Great Britain, at 5.15.—Prof. O. H. P. Prior: French Rhythm and English Poets in Norman and Modern Times.

Institution of Mining and Metallurgy (Annual General Meeting) (at Geological Society), at 5.30.

Child-Study Society (at Royal Sanitary Institute), at 6.—Dr. J. N. Glaister: The Educational Value of the Order of Woodcraft Chivalry.

Optical Society (at Imperial College of Science and Technology), at 7.30.

FRIDAY, April 16.

Royal Society of Arts (Joint Meeting of the Indian and Dominions and Colonies Sections), at 4.30.—Lieut.-Gen. Sir W. T. Furse: The Work of the Imperial Institute.

Institution of Mechanical Engineers, at 6.—W. Worby Beaumont and L. N. Burt: Modern Development of Paper Mill Plant.

Royal Photographic Society of Great Britain (Pictorial Group), at 7.—R. T. Gibbon: Some Limitations of Photography.

Photomicrographic Society (at 4 Fetter Lane), at 7.—Prof. R. T. Hewlett: Neurotropic Viruses.

Junior Institution of Engineers, at 7.30.—T. L. Allison: Automobile Lighting, Starting, and Ignition.

Royal Institution of Great Britain, at 9.—Dr. A. W. Hill: The Quest for Economic Plants.

Society of Dyers and Colourists (Manchester Section).—F. M. Rowe, E. Levin, A. C. Burns, J. S. H. Davies, and W. Tepper: A New Reaction of certain Diazo-sulphonates derived from β-naphthol-1-sulphonic acid.

SATURDAY, April 17.

North of England Institute of Mining and Mechanical Engineers, at 2.30.

Royal Institution of Great Britain, at 3.—Dr. W. T. Calman: The Shipworm (1).

CONFERENCE.

April 17 and 18.

Society for Experimental Biology (at Marine Biological Laboratory, The Hoe, Plymouth):—Saturday, April 17.—10 a.m. to 1—W. H. Pearsall, J. T. Saunders, B. W. Keen: Symposium: The Regulation of the Environment and its Effect on Plants and Animals. 2.15 to 3.45—E. M. Delf: Some Aspects of the Ecology of Marine Algæ.—A. D. Cotton: Ulva and the Assimilation of Nitrogen.—M. Knight: An Analysis of the Algal Vegetation of the Port St. Mary Coast, I.O.M. (Demonstration); 3.45 to 4.45, Exhibits—C. M. Yonge: Digestive Mechanisms in Mollusca.—G. P. Wells: Contractile Tissues of *Holothuria nigra*.—O. D. Hunt: Studies on Bottom Deposits of the Sea.—F. S. Russell: Plankton Distribution.—H. W. Harvey: Nitrates in Sea Water.—A. Westbrook: Tetraspore Formation in Red Algæ.—M. Knight: Ecological Photographs of Algæ; 4.45 to 6.15—F. S. Russell: Factors affecting the Vertical Distribution of Plankton.—H. P. Hacker: The Grouping of Species into Faunæ.—Sunday, April 18.—4 to 7.—C. M. Yonge: The Crystalline Style in the Mollusca.—G. S. Carter: On the Control of the Velar Cilia of the Nudibranch Veliger.—L. E. Bayliss: Contractility in Plain Muscle.—A. S. Parkes: The Mechanism of the Œstrus Cycle.

CONVENTION.

April 12 to April 17.

Optical Convention (at Imperial College of Science and Technology):—Monday, April 12.—At 12.—The Right Hon. Stanley Baldwin: Opening of the Convention; at 3.30—Sir Frank Dyson: Presidential Address.—Tuesday, April 13.—At 10 to 1 and 2.30 to 5.—Reading and Discussion of Papers.—Wednesday, April 14.—At 10 to 1 and 2.30 to 5.—Reading and Discussion of Papers; at 5.30—C. R. Darling: The Optical Lantern as an aid to Teaching (Lecture); at 8.30—Prof. G. Elliot Smith: The Eye and its Functions (Address).—Thursday, April 15.—At 10 to 1 and 2.30 to 5.—Reading and Discussion of Papers; at 5.30—W. Taylor: The Manufacture of Optical Elements (Lecture); at 8.30—J. R. Wharton: Lighthouses and the Optical Apparatus used in them (Lecture).—Friday, April 16.—At 10 to 1 and 2.30 to 5.—General Meeting for the Reading and Discussion of Papers; at 4.30—Dr. E. E. Fournier d'Albe: The Optophone (Lecture); at 8.30—Prof. A. S. Eddington: The Largest and Smallest Stars (Address).—Saturday, April 17.—At 10 to 12.—Reading and Discussion of Papers; at 12—Concluding General Meeting.

CONGRESS.

FRIDAY, April 16.

Congress of the Incorporated Association of Hospital Officers (at Central Hall, Westminster).—Miss R. E. Derbyshire: The Nursing Requirements of a Modern Hospital.—E. W. Morris: The Geographical Distribution of Hospitals in Relation to Community Requirements.

EXHIBITION.

April 12 to April 27.

International Forestry Exhibition (at Milan).

INTERNATIONAL MEETING.

April 16 to April 20.

International Society of Medical Hydrology (Annual Meeting will be held in Czecho-Slovakia). (Particulars from Dr. E. P. Poulton, at 36 Devonshire Place, W.1.)

SATURDAY, APRIL 17, 1926.

Constitution of the University of London.[1]

THE Royal Commission on University Education in London—the "Haldane Commission"—was appointed in 1909 and its final report was issued in 1913. In August 1913 a Departmental Committee was appointed to report as to the steps by which effect should be given to the scheme of the report of the Royal Commission, but that Committee abandoned its labours soon after the outbreak of War.

The Departmental Committee, which reported last month, was set up in October 1924 with Lord Ernle as chairman. In February 1925, however, Mr. Hilton Young was appointed chairman on Lord Ernle's retiring for reasons of health. The terms of reference to the Committee were:

> "To consider the Final Report of the Royal Commission on University Education dated 27th March 1913, and, having regard to present circumstances and after consultation with the persons and bodies concerned, to indicate what are the principal changes now most needed in the existing constitution of the University of London and on what basis a Statutory Commission should be set up to frame new Statutes for the University."

In the introductory section of the report the Committee expresses high appreciation of the analysis and of the ideals presented by the Haldane Commission, but says:

> "A careful examination of the Haldane Report and the knowledge which we have acquired of the progress and development of the University, particularly since the war, have led us to the conclusion that it would be impracticable to attempt to give effect to some of the major recommendations of the Commissioners. There are other recommendations which require modification to meet altered circumstances, and there are others, again, which the University has substantially adopted. . . . We conceive our terms of reference as conferring on us the duty of devising an immediately practicable scheme for the better government, organisation and development of the University to which effect may be given by way of a Statutory Commission, and we are convinced that with the lapse of time and material change of circumstances some of the main recommendations of the Haldane Report have lost their force, and that the ground for attempting to impose such an entirely new constitution on the University as the Report proposed no longer exists. A practicable scheme of reform and reorganisation must, in our opinion, be evolutionary rather than revolutionary and build as far as possible on existing foundations. Certain characteristics peculiar to the University of London have become firmly established, the University has developed greatly during the past twenty-five years, even though hampered by serious constitutional defects. For the removal of those defects we are obliged to recommend some fundamental changes."

---

[1] Board of Education: Report of the Departmental Committee on the University of London. Pp. 76. (London: H.M. Stationery Office, 1926.) 1s. 3d. net

Approaching the problem in the spirit indicated by these passages from the report, the Committee has found it possible to present, in a relatively short report, its own reasoned views and recommendations, together with a discussion of the main points on which divergent views were submitted to it in oral or written evidence. The Committee confined its attention to broad constitutional issues; thus the question of where and how the central offices of the University should be housed—rather a prominent question at present—did not call for consideration by it.

The subject of the external side was considered early, and after discussion and inquiry of the value of the examinations for external students, the conclusion was reached that, "in the view of the whole Committee these examinations have in the past served, and will in future serve, a useful purpose." It is gratifying to learn that on the evidence before it the Committee noted with satisfaction the steady growth of understanding, interaction, and good feeling between the internal and external sides of the University.

Another section of the problem before the Committee—the question of incorporation—appeared, when examined closely, to present no serious difficulty. There are two, and only two, "Colleges incorporated in the University"—University College and King's College. The Haldane Commissioners were of opinion that incorporation should be extended. The Departmental Committee, with the history of thirteen more years on the table, does not recommend the incorporation of other colleges; at the same time it does "not urge the disincorporation of University and King's Colleges." The view is that colleges should "have liberty in agreement with the University to achieve either disincorporation or incorporation."

The pregnant chapters in the Report are those headed, respectively, "The University and its Colleges," "Finance," "The Government of the University," and "The Schools of the University." In these the Committee discusses the facts and considerations which have determined its recommendations as to certain changes in the constitution of the University. These chapters give an attractive, clear, terse and pointed account of the present position and of the advantages which the changes recommended are designed to secure. That account should be read as a whole, for the proposed constitution must be fully envisaged before its effectiveness can be estimated, and the objection or difficulty which may seem to affect it at one point may, in practice, be ruled out at another.

In due course the general scheme recommended as for the guidance of a Statutory Commission will no doubt be subject to criticism and suggestion. Indeed, on a point of primary importance—the only matter of divergence within the Committee—one member of the Committee has presented a 'minority report,' and on that point readers of the main report have in its text the grounds upon which all the other members of the Committee based their recommendations.

The recommendations of the Committee are summarised under twelve heads: (1) The Council, (2) The Senate, (3) Standing Committees of the Senate, (4) The Academic Council, (5) The Council for External Students, (6) The Collegiate Council, (7) The University Extension and Tutorial Classes Board, (8) The Matriculation and Schools Examinations Board, (9) Faculties and Boards of Faculties, (10) Schools of the University, (11) Examinations, (12) The Principal.

Of these, No. 6 would give effect to the view that the "Institutional Element of the University is sufficiently important and distinct to justify not only representation on the Senate, but also the creation of a special standing committee of the Senate." This committee, designated "The Collegiate Council," would consist of the Vice-Chancellor, the Principal, the seven members of the Senate appointed by seven named institutions, the two members appointed by the Medical Schools, with possible additional members added by the Senate as representatives of institutions or groups of institutions, the Principal of the University to be chairman of the Collegiate Council.

Recommendation No. 12 includes that the Principal

> "shall have unrestricted rights of attendance and speech at all meetings of the Council [of the University], the Senate and the standing committees of the Senate, and it shall be his duty to assist them with his advice. He shall be Chairman of the Collegiate Council but he shall not be a member of the governing body of any School of the University."

It is not to be anticipated that these proposals will elicit any serious questioning, but the position, powers, and constitution of "The Council of the University," summarised in Recommendation No. 1, and the matters of policy and of administration which are set out in the Report as in relation to that recommendation, are sure to be subjected to searching examination. Recommendation No. 1 is therefore quoted here in full:

> "There shall be a Council of the University consisting of:—The Chancellor, the Vice-Chancellor, the Chairman of Convocation, Six members appointed from their own number by the Senate, Four members appointed by the Crown, Two members appointed by the London County Council, One member co-opted at the discretion of the remainder of the Council.
>
> "The Council shall control the finance of the University, and in particular it shall have final authority in the allocation of university funds, but in dealing with financial matters directly affecting educational policy it shall give the Senate a full opportunity of reporting.

> "The Council shall have power to negotiate with, and receive money from, grant-giving bodies on behalf of the University as a whole and of any of the Schools of the University including the Incorporated Colleges.
>
> "The Council shall appoint a Chairman from its own number."

With this should be read from Recommendation 2: "The Senate":—

> "The Senate shall elect the Vice-Chancellor. . . .
>
> "The Senate, subject to the financial decisions of the Council, shall control the educational work of the University, but it shall have power to delegate the performance of such duties as it thinks fit to its standing committees and other bodies."

In his minority report, Mr. Lees-Smith presents objections to the constitutional position of the Council as recommended by the Committee, and he recommends "that the representative Senate should be supreme in finance as in other fields, but should have a statutory 'Finance Council,' with the same membership as that proposed in the Report for the supreme University Council."

The recommendations which the Committee makes as to the constitution commend themselves at sight on the ground—a ground, however, to which the Committee does not refer—that the proposed allocation of functions follows in the main the lines that have proved satisfactory in all the newer universities of England and in all those of Scotland. The Report itself presents discussion, explanation, and argument which leave little strength in the objections that witnesses put to the ideas which the Committee had formulated as the inquiry proceeded.

It must be recognised that any argument from the success of corresponding schemes in other British universities does not really carry far; for in size and in complexity the University of London is *sui generis*. As to *size*: from the latest statistics published by the University Grants Committee it appears that, excluding Oxford and Cambridge from the totals, the London institutions comprised in the University of London had of full-time students 8955, while all other university institutions in England had 11,672. Of part-time students London had 7442; other institutions in England 3324. Again, the recurrent grants made by the University Grants Committee were: to London institutions, 376,270*l.*; to others in England, 386,800*l.* As to *complexity*, the Report of the Committee says:

> "There are now 38 Schools of the University ranging from large colleges with several hundreds of internal students to small institutions with few or no internal students and including on the one hand colleges providing undergraduate instruction in nearly all the staple subjects of a normal undergraduate curriculum, and on the other institutions, or departments of institutions devoted entirely to postgraduate study or research in a limited range of subjects."

The recommendations of the Committee mean that the whole amount of the grants made by the University Grants Committee and by the London County Council in respect of constituent institutions of the University would be passed in block to the council of the reconstituted University for distribution as the council might decide. Thus in this important matter the proposed University Council would bear a responsibility with which that now resting on the council of any provincial university in England is as little comparable in scale as it is in complexity. It is to be noted, however, that as the Committee has pointed out, at several stages, not only before the determination of this block grant but also during its currency, the Council of the University would be in effective communication with the University Grants Committee, and further, that in "dealing with financial matters affecting educational policy the Council shall give the Senate a full opportunity of reporting." It might well be also that the smooth starting of the proposed new constitution would be effectively aided in practice by the observations with which the University Grants Committee announced its grant to the Council of the University.

The Committee appears to have tackled successfully the problem of presenting, in outline, a reasoned scheme for such amendment of the constitution of this great University as would provide machinery for its government and administration, sufficiently well-knit to avoid waste of effort, and sufficiently flexible to adapt itself to work in the varied fields in which the University operates.

There are, however, some considerations which, if not faced before effect comes to be given to the recommendations as a whole, may prove detrimental to the scheme. These turn on the fact, which is fully recognised by the Committee, that "the University on its teaching side is organised mainly on a collegiate basis." It is in this collegiate basis of its parts that the University of London differs essentially from the newer universities of England. The resources of its schools are in varying degree in the form of buildings, endowments, and fees and other income liable to fluctuation. A large part of the fluctuating income comes from the grants, national and local, which in the case of London the Committee recommends should be paid in block to the University for allocation to its colleges and other schools. Now, some of these institutions perform valuable functions which are not regarded as university work; many of them have received, both for their university work and for their other activities, valuable annual support and liberal endowments from donors more appreciative of specialised work than of the far-flung usefulness of the University. Not a little of this support has been given for work that is definitely university work but in particular institutions. Considerations turning on such facts as these are bound to give rise to ideas, and indeed fears, that would retard the development of the institution which the Committee desires to promote.

Relatively well-endowed or well-supported schools of the University may fear that the payment of grants in block for allocation within the University may in practice to some extent discount the benefits of their separate resources. Prospective benefactors may find in it reason to hesitate to be generous to a particular institution or in respect of particular aims which they desire to forward.

With the University in the hands of a well-constituted Council and Senate, such fears or hesitation should not materialise; but now is the time to prevent harm from their emergence. The Committee has aimed at an evolutionary rather than a revolutionary scheme of reform and reorganisation. Well-judged application of public support has been the dominant element in the environment of the several institutions of the University, and there should be no apparent risk of serious change or unsettlement in this influence. Some reassurance on this matter appears to be desirable, and it would be well that national and local grants continued to be at least earmarked in the initial stages of the proposed changes. Even now the list of recurrent grants made by the University Grants Committee shows that, in the case of provincial university centres, separate grants are made to six colleges—five in England and one in Scotland—each presumably doing good university work for its region although not incorporated in the university.

Italian Alchemical Manuscripts.

Sulle fonti storiche della chimica e dell' alchimia in Italia. Per Dott. Giovanni Carbonelli. Tratte dallo spoglio dei manoscritti delle biblioteche con speciale riguardo ai codici 74 di Pavia e 1166 Laurenziano. Pp. xix+218. (Roma: Istituto Nazionale Medico Farmacologico, 1925.) 300 lire.

THE great libraries of Italy form one of the happiest hunting-grounds for the seeker after ancient alchemical manuscripts. Dr. Ernst Darmstaedter's exciting discovery last year of a Latin version of Geber's "Book of Mercy," up to that time known only in its Arabic dress, is almost certainly merely a foretaste of what is to come. In the practically unbroken tradition of culture in Italy, extending over a couple of millennia, the accumulation of precious documents has found a peculiarly favourable atmosphere, and the International Committee which is now conducting a census of alchemical manuscripts in Europe will doubtless unearth its greatest treasures in the land of Dante—who consigned all alchemists to a special corner of the Inferno.

The part played by Italy in the scientific renaissance of the twelfth and thirteenth centuries and in the transmission of knowledge has scarcely received the recognition which is its due. In South Italy and in Sicily, under the Norman sovereigns, the translation of scientific works and the dissemination of learning went on apace; in Sicily, for example, the "Almagest" appears to have been translated for the first time into Latin from the original Greek, in 1160 or thereabout, while on the practical side it has been suggested with every probability of truth that the discovery of alcohol was made in South Italy in the tenth century. Although conditions in the northern portions of the country were not so favourable, the commercial relations between Venice and Pisa and various regions of the East led to the establishment of Italian colonies in Constantinople, and in this and other ways a transmission of knowledge and a steady intercommunication between scholars was rendered possible. Among the translators of the north of Italy may be mentioned Burgundio of Pisa, who translated ten books of Galen, and Pascalis Romanus, who, says Prof. C. H. Haskins, can be "almost certainly identified with the translator from the Greek, in 1169, of the curious book known as the Kiranides."

There is, therefore, every reason for great expectations from the Italian manuscripts, and particularly so when we recollect that Italy is also the home of painting. The Muslim dislike of representations of anything endowed with life reacted upon the illustration of books, with the result that very few figures of any sort are found in Arabic alchemical manuscripts; while in most of Europe the alchemists do not shine conspicuously as artists. Such delightful drawings as those which are found in a British Museum manuscript of the "Ordinall of Alkimy," by the Bristol alchemist Thomas Norton, are noteworthy as much for their rarity as their beauty, while in the printed books the figures of apparatus do not often reach the level of those in the 1545 Geber.

With our appetites thus whetted we may turn to Dr. Carbonelli's sumptuous volume and sample his fare. Our first impression is one of complete satisfaction, for it is produced by the sight of his numerous and very attractive illustrations. The coloured frontispiece is a reproduction of Giovanni Brueghel's picture entitled "Elemento del Fuoco," which was probably painted in 1608 for the Cardinal Federico Borromeo, and shows a variety of chemical reagents and apparatus. The muffle in the centre of the picture would not look at all out of place in a modern laboratory, while the bottle of mercuric oxide occupies a position ominous of its future importance. Of the other illustrations we can refer to only a few. Those which offer the greatest appeal are Andrea Orcagna's fresco of the "Alchimisti e falsificatori" in the Tenth Bolgia of Hell, and the drawings of apparatus on pp. 133 to 138. There are also hypothetical portraits of Hermes, Geber, Avicenna and Galen, and a beautiful illuminated page from a manuscript of a work by Albertus Magnus. Altogether there are 242 photographic reproductions, splendidly executed and admirably selected, and for these alone the book is well worth the comparatively modest price asked.

When we leave the illustrations and turn our attention to the letterpress, our first impression of satisfaction will probably wear off. Dr. Carbonelli has unfortunately chosen to make excerpts from the manuscripts and to connect them up into a narrative. The effect thus produced upon the reader is one of exasperation, who either finds himself cut off in the course of a most interesting passage from the manuscript or else is suddenly plunged from Carbonelli into the middle of a treatise of the beginning of which he knows nothing. In spite of this regrettable habit, however, the author has succeeded in making his book attractive by his unerring instinct for the curious and unusual; perhaps no other book on alchemy in recent years has provided such varied and stimulating material. Thus, in Section IV., Dr. Carbonelli describes certain magical and alchemical manuscripts written on lead and silver. At Florence there is a manuscript of this kind, consisting of nine leaden leaves, pierced with two holes and held together by two cords and a little rod of lead. The writing is of the first half of the sixteenth century. On the first page, in Gothic letters, is inscribed: *Benedicta lapidem* (sic) *prima materia est.* Below is an equilateral triangle, and below that again the following phrase: *Ego sum Ambagasar quo dabo a tibi veri secretum secretissimum noster.* In the remaining leaves many of the well-known alchemical sentences occur, such as *Mercurius noster non est mercurius vulgi*, and *In rerum multitudine ars nostra non consistit.* Directions are given for preparing the elixir, which, in addition to its power of transmutation, will cure any incurable disease, "so that you may eat and live a long time upon the earth—supposing, that is, that you observe the Divine Laws."

A very valuable feature of the book is the inclusion at the end of several glossaries of alchemical names, extracted from manuscripts in the author's possession and elsewhere. The number of Arabic terms carried over bodily into medieval European alchemy is astonishing, and the corruption which they have undergone in many cases renders them almost unrecognisable in the absence of glossaries. Knowing, for example, that *leserab* means lead, it is not difficult to see that this word is a corrupt rendering of *al-usrub*, and when *anthigar* is said to signify borax, one can easily trace the derivation from *al-tinkar*; but it is doubtful if these and similar words could have been identified—at least with certainty—in the absence of a vocabulary.

As a whole, Dr. Carbonelli's book reminds us of a shop-window filled with the most attractive wares; we are fascinated by the treasures exposed, but we want to take them out of their setting and examine them carefully one by one and put them in a more suitable environment. Any chemist who feels that he cannot afford to give 300 lire for a book must on no account look at it, or he will inevitably break all resolutions of economy; if he does not succumb until p. 116, the double-page drawings there will certainly complete his downfall.

E. J. Holmyard.

The Winning of Petroleum.

Oil-Field Exploration and Development: a Practical Guide for Oil-Field Prospectors and Operators; with which is Incorporated a Discussion of the Origin and Distribution of Petroleum, and Notes on Oil-Field Legislation and Customs. By A. Beeby Thompson. In 2 vols. Vol. 1: Oil-Field Principles. Pp. xxiv + 546 + 32. Vol. 2: Oil-Field Practice. Pp. xxiv + 547-1177 + 32. (London: Crosby Lockwood and Son, 1925.) n.p.

The subject of oil-field engineering is a difficult one to deal with in a radical manner within the space of two volumes, but whatever Mr. A Beeby Thompson's work may lack in this respect is more than compensated by the amount of information it contains. Whilst we may not have a great deal to learn from America in regard to the geological and refining branches of the petroleum industry, there is no doubt that oil-field practice there is considerably ahead of that adopted by British oil-field engineers. It is a little disappointing to find, therefore, that the author, who is as well acquainted with American drilling methods as the practice of other fields, has added very little to the information given in his earlier books on the subjects of drilling, fishing, and water exclusion.

In the first volume, more ground has been covered, in dealing with oil-field principles, than one would deem possible in the space available. The work of many investigators, augmented by the practical experiences of the author, has been brought to bear on the problems under discussion, but the arguments are inconclusive.

The chapter dealing with the origin of oil is well written, and the many theories advanced have been treated with great care. The formation of oil-fields makes interesting reading, but we would wish the portion dealing with the causes of oil-field pressures had been treated in more detail.

Whilst there are many books on geology, few of them deal with that portion of the science which is applied to the location and winning of petroleum, and the sound, practical hints on oil-field mapping, together with the chapter on oil-field structures, should prove of extreme interest and value to the student and beginner in this branch of the industry. The important bearing which surface indications have on such work is exemplified in detail, particularly in regard to mud volcanoes, petroleum seepages, asphaltic deposits, and the general association of sulphurous and saline waters with petroliferous areas, but the conclusions to be drawn from such indications are dismissed in a very few pages.

Much valuable information is brought together within a small compass in the chapters which concern the geology of the various oil-fields throughout the world. Particulars of many of the fields given have not been available in book form hitherto. These chapters are undoubtedly the best in the first volume. The book has been written as "a practical guide for oil-field prospectors and operators," and we feel that the chemical and physical properties of natural hydrocarbons are not dealt with in a sufficiently fundamental manner to serve the purpose intended. In the refining portion, the author deals with the effect of open steam and vacuum distillation clearly, but beyond describing briefly one continuous method of distillation, the reader is left with the impression that the distillation and refining of petroleum generally is a comparatively simple matter.

Errors which should be corrected in any future edition are the reference to the Edeleanu process and to the use of adsorptive materials for the purpose of refining, as being chemical methods; and the reference to cracking in the vapour phase as a commercial proposition. We feel this portion of the book scarcely does justice to the author or those engaged in the refining branch of the petroleum industry.

The second volume, on oil-field practice, is appreciated all the better for keeping until last. The descriptive matter relating to the various methods of oil-well drilling and lining contains much information, notable features being the Hild differential gear for controlling and maintaining torsion on the 'rotary' stem below an arbitrary limit, and a short reference to coring. The specifications for the different types of drilling outfits should prove of use to the field-man.

One point stressed by the author will receive the approbation of all production engineers of experience, namely, the present necessity of employing the services of scientifically trained junior geologists for the collection, examination, and description of samples of the formation passed through. "The driller's phraseology no longer conveys as much information as modern research demands."

Methods of recording and analysing drilling and producing records, not only for immediate use, but also for estimating purposes in the future, and the tabulated drilling costs on various oil-fields, particularly those of recent date, are some of the outstanding features of this volume.

The havoc wrought in many fields through overlying and lower waters entering oil-sands, and how this might be obviated by adopting a uniform casing programme throughout the field, is clearly shown with the aid of a diagram, and is worthy of note by men of experience. Attention is also directed to the danger to casing, in position, of corrosive waters, and also to the importance of chemical analyses of oil-field waters with the view of their identification. These chapters, together with those dealing with the location and isolation of oil-field waters and the various methods employed for the recovery of petroleum, which comprise the bulk of the second volume, prove the author to be a man of wide experience in methods of production. His experiences confirm the opinion shared by many petroleum technologists of experience that the responsibilities of the production superintendent are as great as, if not greater than, those of the drilling superintendent.

Mr. Beeby Thompson's views on oil-field equipment, particularly where internal combustion engines and electric power for oil-field purposes are dealt with, are welcome in literature of this kind, as the application of electricity to production work is still in its infancy. With the necessity for housing oil-field workers in comfortable and sanitary camps, particularly in the tropics, every one will agree, and valuable suggestions are made with this in view. More space might have been devoted to the Chambeau system of sewage disposal for the benefit of those situated in isolated places who are unfamiliar with sewage problems generally, and this simple, but effective, method in particular.

Useful information concerning the design of pumping plant and frictional losses in oil pipe-lines is included, and the chapter on natural gas gives a clear insight into the methods of casing-head gasoline absorption and gas transmission. The work is completed by an appendix giving tables and data which all petroleum technologists will find useful.

As a compilation of facts and knowledge augmented by the personal experiences of the author, the work can be recommended especially to petroleum students and those about to enter the industry, as it deals largely with information of a practical character which scarcely comes within the purview of an academic teacher on the subject, and many of the chapters will prove of interest to the production engineer of experience. The book is well illustrated, and those desirous of pursuing further any of the questions under discussion will find ample and complete references.

Alfred W. Nash.

The Smoke Problem.

The Smoke Problem of Great Cities. By Sir Napier Shaw and Dr. John Switzer Owens. Pp. xvi+301. (London: Constable and Co., Ltd., 1925.) 22*s.* 6*d.* net.

It is a significant fact that the thing which first strikes the foreigner on visiting large cities in Great Britain is the smoky atmosphere and the grimy appearance of the buildings. He wonders how we can tolerate such an environment. It is true enough that most of us do so, and it may be, as one writer has said, "that thousands of people live their lives from start to finish in the midst of black smoke and have come to regard it as a normal condition of life." Nevertheless, there is a small section of the community who feel very differently on the subject, as the growing mass of literature on the smoke nuisance testifies. The latest contribution is a treatise on the smoke problem of cities by Sir Napier Shaw and Dr. Owens, who for many years have devoted their attention to the estimation of atmospheric impurities in London and other large towns. The most interesting section of the volume is the record of these experiments, namely, the measurements by the standard gauges, which have been set up in various towns, and the results obtained with the dust filter and the jet dust counter, all of which have already appeared *in extenso* in the reports of the Committee on Atmospheric Pollution of the Meteorological Office. The volume includes also a good deal of information borrowed from other sources.

The standard gauge consists of a circular stoneware funnel of 30 cm. diameter, which is inserted into the neck of a large bottle, and the solid deposit which is carried down by rain or blown in by the wind is estimated at stated intervals throughout the year. The character of the deposit varies considerably in different towns, and will naturally depend on the situation of the gauge and the rainfall. For example, the deposit at Malvern, a residential town in a rural district, contains so much as fifty per cent. of wind-blown mineral matter. The soot, amounting to eight per cent., which is estimated by the loss of weight on ignition of the deposit (and may very well contain vegetable matter), curiously enough is free from tar, although the authors find so much as 37 per cent. in domestic soot. The result, as indicative of atmospheric pollution in different towns, cannot be regarded as altogether trustworthy, and I would suggest as a more satisfactory method, the collection of the permanent tarry deposit on glass plates which could be roughly but rapidly estimated by the amount of light obscured from a standard lamp. For the tarry deposit, for which the domestic hearth is mainly responsible, is cumulative in its destructive and disfiguring effects. The free acid, another destructive agent, might also be estimated in the rain water.

There is one statement which, though probably correct, is somewhat misleading, namely, that the soot suspended in the air is not removed by rain. There is no doubt, however, that soot is absorbed by clouds, as it is by fog, and the former when resolved into rain will carry down considerable quantities of soot. Snow will do the same. The chapter on the dust filter and automatic recorder designed by Dr. Owens is one of considerable interest and importance, and probably affords a more satisfactory estimate of air pollution than the gauge referred to. It is an apparatus for filtering a measured volume of air through white filter paper and estimating by the shade of the deposit the extent of impurity. By an ingenious modification the instrument is rendered automatic, so that hourly records can be taken if necessary without supervision. The jet dust counter is a modification of Aitken's dust counter, by which particles of dust are deposited on a cover glass and can be examined microscopically. In this way some curious observations have been made on the nature of the more minute atmospheric particles.

In addition to the above, the authors have collected information on the industrial uses of smoke, on the use of different kinds of smokeless fuel, on the remedy for industrial smoke and a summary of the recommendations of Lord Newton's committee. The latter is a useful addendum; for the report has been very sparsely circulated and is now out-of-print. The book is the most comprehensive account of the subject which has yet appeared. But unfortunately its very comprehensiveness makes the price prohibitive to the ordinary individual whose co-operation is so essential, if this pestilential nuisance is ever to be seriously tackled. The following paragraph is from the recent report of the Coal Commission:

> "We would observe that the three million tons of soot which it is estimated by the Commission are discharged into the air annually are equal in weight to nearly three days' output of all the collieries of Great Britain. In effect the work of over a million for three

days every year is devoted to providing the soot which pollutes our atmosphere."

When one realises that raw coal and coke may and should be burnt in boiler furnaces without smoke, that gas-coke may replace raw coal for domestic use (I use nothing but gas-coke for hot water and heating the living-room), the production of smoke seems a criminal waste of our fuel resources, apart from the heavy cost in health, in the destruction of vegetation, disintegration of masonry and metal work, deterioration, so I am told, of valuable oil paintings, and the outlay in washing and repainting. J. B. COHEN.

Mammalian Palæontology.

Text-Book of Palæontology. By Karl A. von Zittel. Vol. 3: *Mammalia.* Revised by Dr. Max Schlosser. Translated under the direction of Dr. Charles R. Eastman by Lucy P. Bush and Marguerite L. Engler. Translation revised, with Additions, by Sir Arthur Smith Woodward. Pp. viii + 316. (London: Macmillan and Co., Ltd., 1925.) 25*s.* net.

THE completion, after twenty-five years, by the issue of a volume dealing with mammals, of that translation of v. Zittel's "Grundzüge der Paläontologie" for which the late C. R. Eastman was responsible, is creditable to its publisher, and may, we hope, be a symptom of a renewed interest in palæontology in Britain.

The "Grundzüge" is the one essential book to the working palæontologist, because it lists the great majority of genera of fossil vertebrates, indicating the more important synonyms and referring them to families. Of these families, and all larger groups, short and usually excellent diagnoses are provided; only those who have never endeavoured to draw up similar condensed statements of the characters which define groups will complain that some of the animals do not really exhibit the 'diagnostic' characters of the groups within which they are included. To these descriptions are added more detailed accounts of the structure, in the main naturally of the skeleton, and sometimes indications of phylogeny; and the book ends with an excellent general account of the distribution in space and time of the more important mammals.

The title adopted for the English edition, a "Text-Book of Palæontology," neither correctly translates the German title nor expresses the character of the book. Consisting as it does of a mass of facts with no indication either of methods of work or of the general theory of the subject, it is by itself of little use to the beginner, and requires to be supplemented in some way, either by a teacher or by some, as yet unwritten, introduction.

Of the German version, four editions have appeared, the last in 1918 and 1923, and a fifth is in preparation. The present translation, which was left nearly all in type, though unrevised, at the death of Dr. Eastman in 1918, has been to some extent brought up-to-date by Sir Arthur Smith Woodward. This long delay has, however, resulted in the omission of many important discoveries recorded in the German edition of 1923. Of these the most serious is that of all reference to the work of Dr. Pilgrim, work which is fundamental in that it gives us an understanding of the age of the successive faunas of India, and for the first time enables us to use them in discussion of phylogeny and of migration.

There are many other omissions of important finds: Broom's account of the skull of Polymastodon; Dr. Matthew's Eodelphis, Palæoryctes, Zanyrictes; Stehlin's so-called Chiromyids; Osborn's skulls of Bathyopsis and Eotitanops, all things of first-rate importance published before 1923, are not referred to. The American and Swedish work on the fossil mammals of China and Mongolia is perhaps too recent to expect. Finally, it may be pointed out that the German volume containing the lower vertebrates in addition to the mammals costs 18*s.*, whilst the two corresponding English volumes are 50*s.* D. M. S. WATSON.

Our Bookshelf.

Principles and Practice of Farm Book-keeping: a Text-Book for Agricultural Students. By Leonard F. Foster. Pp. viii + 476. (London: Gee and Co. (Publishers), Ltd., 1925.) 15*s.* net.

THE time has come when farmers and accountants must study each other's requirements, for the business of farming cannot now be conducted by the free and easy methods of the past. The farm requires special consideration in its book-keeping department, for in that, as in many other things, it differs widely from the ordinary undertakings of commerce. Farmers who have sought the aid of accountants in coping with their book-keeping problems have very often been unable to obtain that meed of help which they may have expected, because the ordinary cut-and-dried methods of account have not been varied to meet their special need. It is probable that the demand for special agricultural accountancy is only now becoming strong enough to make itself felt, and Mr. Foster's book is one of the first serious attempts by a qualified accountant to expound the principles of book-keeping as applied to the farm departments.

It is a welcome book, because there are a large number of people, students and practising farmers alike, who are looking for something of the sort. It is a good book, because it covers the subject with which it professes to deal, and develops it in easy and definite stages from the first broad principles to the special technical applications found in agriculture. It contains a wealth of illustration in the form of specimen accounts, and the method of expression used is at once clear and sufficiently human to maintain the reader's interest.

Mr. Foster is careful to state that his work does not do more than touch lightly on the subject of farm costing. The difference between financial and cost accounts is not always clearly seen by persons who are new to book-keeping. Theoretically both may be necessary to the really efficient management of a large holding, but for the immediate purposes of sound trading and daily guidance, it is the financial accounts which are so very important. It is to be hoped that more accountants will follow Mr. Foster's example and develop the subject of farm book-keeping to the mutual benefit of their rural clients and themselves.

C. H.

The Science of Soils and Manures. By J. Alan Murray. Third edition, revised and enlarged. Pp. xiv + 298. (London: Constable and Co., Ltd., 1925.) 12s. 6d. net.

THE third edition of this text-book, issued under a slight change of title, aims at bringing its subject up-to-date for the use of students of advanced university standard. The considerable recent advances in our knowledge of soil structure and chemistry, and in the bearings of soil biology on plant growth, have been incorporated, compensation of space being made by judicious omissions of certain ideas and methods which are either out-of-date or have failed to fulfil their promise of usefulness. A concession to more advanced students is made by the inclusion of pertinent mathematical data in the appendix, to which are also removed from the text various tables only required for occasional reference, whereby the handiness of the book is considerably increased.

Certain features of the work deserve special commendation. The horticultural, as opposed to the agricultural, aspect of the fertiliser problem is considered, and manurial tables are included applicable to garden crops, of which the requirements vary considerably. Attention is given to the various manufacturing processes of artificial fertilisers, with illustrations of plant actually in use, thus enabling the student to obtain a clearer idea of what he is really dealing with when applying manures. A useful chapter on fertiliser valuation is included, concrete examples being given, illustrating the misleading nature of the system of unit prices, and showing simple methods by which the actual value of fertilisers to the farmer can be calculated.

W. E. B.

Outlines of Qualitative Chemical Analysis. By Prof. Frank Austin Gooch and Prof. Philip Embury Browning. Fifth edition, revised. Pp. viii + 184. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 7s. 6d. net.

THIS work supplies a " systematic scheme of analysis " for the usual set of commoner basic and acidic ions. One would like to see these somewhat hackneyed limits extended to include a few 'rare' elements. It is difficult to know where to stop, but surely it is time that ordinary courses in chemistry dealt with such commercially important elements as, for example, titanium, molybdenum, tungsten, and possibly even thorium.

So far as it goes, the book deals excellently with the subject. An introductory chapter treats briefly but well of the ionic principles underlying the reactions; and the usual systematic examination, condensed into tabular form with commentaries on important points, is supplied with ample references to this first chapter. The methods given are well arranged and up-to-date, and a student who works carefully through them and answers the questions set should learn some chemistry as well as 'tests.' The book is marred by a final short chapter on some haphazard tests for a few commoner organic compounds—acids, alcohols, sugars, alkaloids—a chapter which, with little system and no instruction in principles, is decidedly inferior to the preceding matter.

The book is well turned out, and few printing errors have been noticed.

T. W. H.

Half-Hours with the Telescope: a Popular Guide to the Use of the Telescope as a Means of Amusement and Instruction. By R. A. Proctor. Revised and brought up to date by Dr. W. H. Steavenson. Pp. xii + 131 + 7 plates. (London: Longmans, Green and Co., Ltd., 1926.) 5s. net.

THIS is the fifteenth impression of this book since its inception in 1868. Under Dr. Steavenson's revision, a number of necessary corrections and additions have been made with the view of continuing its former usefulness. New illustrations have been substituted throughout. It may be mentioned that the book is essentially one for the amateur possessing a telescope which he is prepared to use. He will then find in this little publication an excellent guide to the many objects of interest within reach of modest telescopic means, together with a simple account of the construction of his instrument and valuable hints for its successful use. The book is of pocket size, and the type is clear. There are, however, a few misprints, as on pp. 59, 70, and 107. A brief note on the nomenclature of the stars, or a reference to the British Astronomical Association Handbook for 1924 (in which all star catalogues are briefly described), would have been helpful to the beginner. From a cursory glance at the pages, the would-be purchaser might be inclined to object to the price, but its worth will be readily admitted by a purchaser who, with its aid, has spent some very profitable half-hours with his telescope.

Sympathetic Training of Horse and Man. By Major T. S. Paterson. Pp. xi + 205 + 8 plates. (London: H. F. and G. Witherby, 1925). 12s. 6d. net.

THIS book is described as " a Handbook on Present-day Training in Equitation," and, as the title indicates, it includes the necessary training of both man and horse in the methods by which that remarkable sympathy between horse and man can be established. As the author so admirably shows, successful equitation depends on the establishment of this link. Scientifically, we may be permitted to doubt whether the material indications of intention (the rein, spur and so forth) are the true media of communication between man and horse. The manner in which the dog, too, divines his master's mind, is scarcely capable of simple explanation. A well-written and attractive book.

Letters to the Editor.

Spinning Electrons and the Structure of Spectra.

RECENTLY Uhlenbeck and Goudsmit (NATURE, February 20, p 264; see also *Naturw.*, November 20, 1925) have directed attention to the fact that a number of features of multiplet structure and the anomalous Zeeman effect can be described by assuming the electrons in the atom to possess an inherent magnetic moment, pictured as being due to a spinning motion of the electron about an axis of symmetry. This moment must be considered as having a magnitude of 1 or 2 Bohr magnetons (about 10^{-20} c.g.s. units), depending on what rules one assumes to govern the orientation of the axis with respect to an external magnetic field. The above-named authors discuss the advantages which such a view brings with it, but fail to point out some serious difficulties.

If it is permissible at all to use pictorial concepts such as the word 'spinning' evidently implies, it must also be permissible to speak of the 'dimensions' of an electron. These dimensions would then have to be taken as of order of magnitude 10^{-13} cm. To give a magnetic moment around 10^{-20}, the internal velocities would have to be exceedingly close to that of light. Now the elementary unit of magnetic moment, the Bohr magneton, is derived from considerations of the *orbital* motions of electrons with velocities *much smaller* than that of light (W. Pauli, jun., *Zeit. f. Phys.*, 31, 373, 1925), in which the internal structure of these electrons does not enter at all, so that they can be regarded as point charges It is hard to see, then, why this elementary unit should also be characteristic of the internal motion of the electrons in spite of the high velocities involved, and that with a precision which would have to be considerable, if the measurements on the anomalous Zeeman effect were to be explained in this way.

Quite aside from this objection, the validity of which could perhaps be questioned, since we may not be justified in applying the classical concepts of kinematics and electrodynamics to the case of the structure of the electron, even if we only wish to obtain rough estimates, the following difficulty arises. In order to account for the observed Zeeman effect by the hypothesis of Uhlenbeck and Goudsmit, it is necessary to assume that an orbital electron always has the same magnetic moment, of the order of a Bohr magneton, no matter in what orbit or in what atom. One is thus led to expect that this also remains true when an electron forms part of the nuclear structure. But then the nucleus, too, will have a magnetic moment of the order of a Bohr magneton, unless the magnetic moments of all the nuclear electrons just happened to cancel. For such an additional moment of the nucleus there is no place in the theory of the Zeeman effect, and the probability that in all atomic nuclei the magnetic moments of the electrons neutralise seems *a priori* to be very small.

The new hypothesis, therefore, appears rather to effect the removal of the family ghost from the basement to the sub-basement, instead of expelling it definitely from the house. R. DE L. KRONIG.

Theories of Adsorption and the Technique of its Measurement.

SEVERAL years of measurement of sorption in the University of Bristol laboratory by the simple and searching method of the sorption balance (for description see *J. Am. Chem. Soc*, 1924, 46, 2781, and March 1926, 48, 690) have taught us two things: First, most of the published data on the sorption of gases and vapours possess no quantitative significance because they refer to insufficiently cleaned surfaces. Second, the behaviour of a surface when cleaned from pre-existing impurities assumes a different and highly significant form It is usually supposed that mere heating of a substance like charcoal to, say 400°, with exposure to an ordinary vacuum, will completely remove previously sorbed gases. This is by no means the case. For example, carefully prepared sugar charcoal, which had been activated by superficial oxidation at about 1200°, was given an exposure for five hours at 450° to a vacuum of 10^{-6} mm, and was afterwards found to sorb a maximum of 17·5 per cent. of its own weight of nitrous oxide in a protracted series of experiments. The amount of nitrous oxide sorbed was raised to no less than 26·5 per cent. by the simple expedient of re-evacuating the charcoal at 450° after its saturation with nitrous oxide, and then repeating the measurements. Similar behaviour has been observed in many other cases; for example, the observed sorption of such inert substances as hexane or decane may be increased several fold by repeating the evacuation after the charcoal has been saturated with the hexane or decane to displace other impurities from the surface

It is evident that published data are too uncertain in magnitude to permit of accurate comparison of the sorption of various substances for the testing of conflicting hypotheses. The second influence of these neglected residual impurities is to change the character of the curve representing the dependence of the sorption upon the pressure or vapour pressure The ordinary form of sorption curve as obtained in the presence of tenaciously sorbed impurities shows steady increase with increase of pressure. The same surface when cleaned gives not only much greater sorption, but also the sorption is practically complete at comparatively low pressures, remaining constant at a saturation value as the pressure is further increased. With methyl alcohol and with toluene, for example, the pressure of the vapour can be increased five to twenty fold without appreciable increase in the amount adsorbed once the saturation value has been attained Moreover, the adsorption on clean surfaces is nearly instantaneous and is perfectly reversible. It therefore becomes evident that the existence of a saturation value for sorption of vapours by charcoal is normal and characteristic.

There are at present three competing theories of adsorption: First, the monomolecular films of Langmuir (1916), Henry (1922), and others, in which interaction is confined to molecules of gas or vapour in actual contact with molecules of the surface; second, the polymolecular films of Polanyi (and Williams, *Proc. Roy. Soc.*, A, 1919, 96, 307) and Lamb and Coolidge (1920), where it is assumed that at distances many molecular diameters away from the solid surface, there is still a powerful attraction of gas or vapour molecules towards the surface, producing a film of compressed gas or even liquid; third, the capillary condensation hypothesis of Gurwitsch, 1915, and Patrick, which assumes that liquid is condensed in bulk in the pores of a porous solid such as charcoal or silica gel.

The objections to the Gurwitsch-Patrick hypothesis as a general theory are that it ignores the existence of adsorption upon plane non-porous surfaces, and that it does not account for the adsorption of the layer of molecules of liquid in actual contact with the solid. Furthermore, calculation from the well-known thermodynamic formula connecting vapour pressure with pore diameter for a liquid in a capillary shows that the greater part of adsorption is observed at pressures so low as to correspond with pores of diameters comparable with molecular magnitudes. Hence, even from this, one may argue that here true adsorption is responsible because the adsorbed molecules are all in direct contact with the molecules of the surface. Of course, whenever a surface coated with a mono-molecular film is shaped as a pore and exposed to nearly saturated vapour, liquid may condense in such a capillary.

The evidence for the thick compressed film of Polanyi is weak. The unknown constants of the formulæ based upon the assumption of a multimolecular film are determined by using some of the actually measured sorption data; and the expression then fits the remaining sorption data at other temperatures, etc. However, any one of the other theories will do as much. Again, many experiments have shown apparently thick films, but only with materials such as tarnished metals, glass that had been washed out with water, etc., where the true surface was unknown. Williams's derivation indirectly led to a determination of the thickness of the adsorbed layer; and he found from his study of existing data for gases and vapours that the thickness was of molecular magnitude except in the case of charcoal exposed to saturated vapour of liquid argon, where alone it corresponded to several molecules thick. Further, Henry's formulæ for monomolecular films are closely similar to those of Williams.

Much direct evidence has been brought in support of the monomolecular film hypotheses. The films postulated differ greatly in respect of packing, relation to the structure of the solid, nature of the binding force, whether truly chemical or due to physical forces or residual valency, etc., but they are alike in explaining all forms of adsorption as due to direct attachment of the adsorbed molecules to the solid surface. The striking fact that in our normal sorption curve the adsorption is practically completed at relatively low pressure affords new and almost conclusive support for the hypothesis of a monomolecular film.

Abraham de Moivre.

IN interesting and valuable communications to *Biometrika*, of the final issues for 1924 and 1925, Karl Pearson set forth certain facts (not all new) which will doubtless result in Abraham de Moivre occupying a more important place than before in the history of mathematics. The results are reached by a careful study of: (*a*) "James Bernoulli's Theorem," and (*b*) a publication of Moivre dated November 12, 1733 Regarding this publication Pearson makes certain statements which require comment, since from them wrong inferences might readily be drawn.

This publication is entitled: "Approximatio ad Summan Terminorum Binomi $(a+b)^n$ in Seriem expansi" and was found bound in with one copy of Moivre's "Miscellanea Analytica," 1730. Pearson remarks:

"Many copies of this work have attached to them a *Supplementum* with separate pagination, ending in a table of 14 figure logarithms of factorials from 10! to 900! by differences of 10. But only a *very few* copies [P. tells of only the one] have a second supplement, also with separate pagination (pp. 1-7) and dated Nov. 12, 1733. This second supplement could only be added to copies sold three years after the issue of the original book, and this accounts for its rarity. Dr. Todhunter in writing his *History of the Theory of Probability* appears to have used the 1730 issue of the *Miscellanea Analytica*, and so never came across this supplement."

Pearson here seems to make two slips: (*a*) in assuming that because this "second supplement" is bound at the end of a copy in the University College Library, it was really a second supplement, (*b*) in stating that this publication was not considered in Todhunter's "History." As a matter of fact, this 'second supplement' appeared in English, except for minor changes, in both the second and third editions of Moivre's "Doctrine of Chances," 1738 and 1756. Todhunter considers this on pages 184, 192, 193 of his "History." Curiously enough, in the latter part of his first article, after having indicated the results of the 'second supplement,' Pearson remarks: "The same matter is dealt with twenty-three years later in the edition of 1756 of *The Doctrine of Chances*, pp. 243-250. Todhunter in his *History of the Theory of Probability*, Arts 324 and 335, passed over the topic most superficially." Did Pearson overlook that a translation of his 'supplement' was thus dealt with in 1756 by Moivre and in 1865 by Todhunter? That this translation appeared also eighteen years before was manifestly not recognised.

Moreover, Moivre prefaces his translation with the statement (which Todhunter quotes): "I shall here translate a Paper of mine which was printed November 12, 1733, and communicated to some Friends, but never yet made public, reserving to myself the right of enlarging my own thoughts as occasion shall require." Hence it is clear that the publication in question was not a 'second supplement' to Moivre's "Miscellanea Analytica," but was first 'made public,' and in English, in 1738. A facsimile of this pamphlet is to appear in an early number of *Isis*. It would be interesting to learn if any other copy of Moivre's original pamphlet is in existence.

RAYMOND CLARE ARCHIBALD.

Brown University,
Providence, R.I.,
February 22.

I am glad that Prof. Archibald's letter enables me to return to the subject of De Moivre's claim to be the first discoverer of the normal curve of errors usually attributed to Laplace or Gauss.

I do not think from what Prof. Archibald has written that he can have seen what he thinks—and possibly may be—the unique copy of the "Approximatio ad Summan Terminorum Binomi." It is in the same type and has the same characteristic species of tailpiece as the "Miscellanea Analytica." It has the same unusual form of pagination as the first "Supplementum", it is printed on the like paper and is of the same format as the first "Supplementum" and the "Miscellanea" About half the known copies of the "Miscellanea Analytica," have *not* the first supplement, and I think it quite probable that the "Approximatio" was only bound up with a few last copies of the "Miscellanea Analytica" issued after November 1733. At any rate, that is where I should seek for it *first*. I said in my paper that De Moivre treated of the same matter in his "Doctrine of Chances," 1756, because that was the edition I was working with. Prof. Archibald rightly says that it was also treated of in the 1738 edition, and then speaks as if the matter in the 1738 "Doctrine of Chances" and again in the 1756 edition was a mere translation "except for minor changes." This is not correct; for the history of statistics most important additions were made in both the 1738 and 1756 editions. The important principle of the 'activating deity' maintaining the stability of statistical ratios does not occur in the 1733 "Approximatio"; it first appears tentatively in the 1738 "Doctrine," where the seven lines of Corollary X are increased to nearly fifty lines, while in the 1756 "Doctrine" this corollary alone occupies some four pages or about 160 lines. Indeed the 6¼ pages of the "Approximatio" become 11¼ pages (of more lines) in the 1756 "Doctrine." As De Moivre appropriately observes, he has reserved to himself "the right of enlarging my own thoughts." That enlargement, developing Newton's idea of an omnipresent activating deity, who maintains mean statistical values, formed the foundation of statistical development through Derham, Süssmilch, Niewentyt, Price to Quetelet and Florence Nightingale. These may be mathematically 'minor' points, but they are vital for the history of statistics, and my reference to these additions in the penultimate paragraph of my paper might have shown Prof. Archibald that I was aware of the differences between the original "Approximatio" and the same dealt with in the "Doctrine of Chances." My error lay in not recognising that in the 1738 "Doctrine," the 6¼ pages had grown to a little over 8, to become 11¼ pages eighteen years later.

As to Dr. Todhunter, I have nothing whatever to retract in my judgment. In his Art 335 he misses entirely the epoch-making character of the "Approximatio" as well as its enlargement in the "Doctrine." He does not say: Here is the original of Stirling's Theorem, here is the first appearance of the normal curve, here De Moivre anticipated Laplace as the latter anticipated Gauss. He does not even refer to the manner in which De Moivre expanded the Newtonian theology and directed statistics into the channel down which it flowed for nearly a century. Almost everywhere in his "History" Todhunter seizes a small bit of algebra out of a really important memoir and often speaks of it as a school exercise, whereas the memoir may have exerted by the principles involved a really wide influence on the development of the mathematical theory of statistics, and ultimately on statistical practice also.

Todhunter fails almost entirely to catch the drift of scientific evolution, or to treat that evolution in relation to the current thought of the day, which influences science as much as science influences general thought. The causes which led De Moivre to his "Approximatio" or Bayes to his theorem were more theological and sociological than purely mathematical, and until one recognises that the post-Newtonian English mathematicians were more influenced by Newton's theology than by his mathematics, the history of science in the eighteenth century—in particular that of the scientists who were members of the Royal Society—must remain obscure

Karl Pearson

Muscular Contraction.

In the *Proceedings of the Royal Society*, Ser. B. Vol. 99, No. 694, December 1, 1925, W. E. Garner has published a paper that has interested us very much, because we are studying the possibility of a similar theory of muscular contraction. There is, however, sufficient difference in the mode in which we formulate our theory to make it worth while to describe our hypothesis. Moreover, we have succeeded in several experiments in producing evidence in support of our suppositions.

A first point of importance is, that measurement of the size of the fibrils in skeletal muscle seems to indicate that the total surface is larger than 20,000 sq. cm. We found that the distance of the transversal discs in muscles of rabbits was 1·8μ ($\pm$0·1) and the distance apart of two longitudinal fibrils 0·8μ ($\pm$0·1). From these values it is possible to calculate that the total surface of the fibrils in one gm. of muscle is 5 sq. m. or less and the surface of the transversal discs (both sides) 1·0 sq. m. In close agreement with these numbers is the surface occupied by all the lipoids extracted from 1 gm. of muscle when spread out on a large water surface and measured on the Adam-Langmuir apparatus. Twelve experiments gave results between 6·7 sq. m. and 7·1 sq. m. This agreement already indicates that the lipoids are spread out in a mono-molecular layer on the surface of the fibrils (and perhaps also of some transversal discs). (Cf. our paper on the bi-molecular layer of lipoids on chromocytes, *Journ. of Exp. Medicine*, 1925.)

Now when we make these same measurements in heart muscle of rabbits, we find much smaller distances between the fibrils, which are about half of those indicated in rabbit skeletal muscle. It is also a remarkable fact that the surface occupied by the lipoids from 1 gm. of heart muscle is about twice as large as that occupied by a similar extract of skeletal muscle. We found 16·6 sq. m. to 17·8 sq. m. in heart muscle.

The change of this lipoid film seems to us a very important phenomenon in muscular contraction. We would suggest a hydrogenation of the lecithin-kephalin molecules that form the principal fraction of the lipoid of muscle (only $\pm\frac{1}{10}$ is cholesterol) under the influence of hydrogenation and the formation of hydro-lecithin and hydro-kephalin. The effect would not only be a change in size from 2 to 1, but also a change in rigidity of the surface of the fibrils. A simple calculation shows that by a change of the total surface of an element having the dimensions $0{\cdot}8 \times 0{\cdot}8 \times 1{\cdot}8\mu$, into one of the dimensions $0{\cdot}8\sqrt{2} \times 0{\cdot}8\sqrt{2} \times (1{\cdot}8/2)\mu$, has the effect of decreasing the surface $\sqrt{2}$ times. We are therefore able to explain the shortening of a muscle fibril to half its length by changing 1·4/2 part of the total surface from lecithin into hydro-lecithin. For, as Leathes has shown, the spreading of the molecule of lecithin is 114×10^{-16} sq. cm., whereas hydro-lecithin gives half this value: 56×10^{-16} sq. cm. Lecithin is semi-liquid and hydro-lecithin a solid crystal powder.

Now it is clear that lactic acid cannot produce this change from lecithin into hydro-lecithin. It can be shown, however, that lactic acid, formed in the anærobic phase of the muscular contraction, has another influence. It acts on the protein in much the same way as hydrogen acts on lecithin in the presence of a catalyst.

It is possible to determine the total surface on water occupied by a certain portion of a protein extract from muscle when spread out on a water surface. In a great number of experiments we were able to show that a protein solution from the skeletal muscle of the rabbit always occupies the same surface on water, the nitrogen content of the extracts being equal. Taking 34,000 as the molecular weight of these proteins, we always find a surface of $\pm 1400 \times 10^{-16}$ sq. cm. for each molecule, which enables us to calculate a thickness[1] of $\pm 30 \times 10^{-8}$ cm at zero-pressure (extrapolated).

---

[1] This value is independent of the molecular weight.

From this number and from the protein content of the muscle, it is possible to calculate that the total surface of all the protein of 1 gm. of muscle would be ±50 sq. m., assuming that all the protein is in the same condition as the protein on the water surface (a highly improbable supposition). Now lactic acid —like other acids—has a striking influence on the size of the area occupied by this protein solution on a water surface. After adding so much lactic acid that the *p*H changes gradually from 6·4 to 4, we find that the area remains practically constant from 6·4 to 5·4 and changes suddenly between 5·4 and 4·8 into one having much smaller dimensions. At about *p*H4 it is not much larger than 450×10^{-18} sq. m.

There is a close agreement between the small quantity of lactic acid required to bring about this sudden change of the spreading of the protein molecules, and the lactic acid produced in a single contraction as calculated by A. V. Hill (0·031 mg. per gm. muscle). Much depends on the buffer value of the solution used for the experiments. If we take a very feebly buffered solution of $\frac{1}{1000}$ mol. KH_2PO_4, so little as ±1·6 c.c. of a tenth molar solution of lactic acid per litre is capable of producing the effect (0·015 mg. per c.c.).

From our experiments with hæmoglobin (*Proc. Roy. Acad. of Sci., Amsterdam*, Dec. 19, 1925) and with other proteins, we are inclined to consider this change in the size of the protein molecule on a water surface under the influence of differences of the *p*H of the solution as a general property of all proteins. We only add here that further increase of the acidity tends to produce the reverse effect, so much so, that the largest surfaces occupied by protein molecules are two to four times larger than those on neutral water. We get on $\frac{1}{4}$ molar hydrochloric acid a film having a thickness of 6·6 to $7{\cdot}5 \times 10^{-8}$ cm. These are considered by us as layers having the thickness of one amino-acid (Cf. de Nouy, *Journ. Biol. Chemistry*, 64, 1925.)

There exists some evidence indicating that hæmoglobin is orientated at some surface inside a red blood cell in such a way that all the hæmochromogen and iron is placed at the surface. By analogy we suggest that the cystine (or glutathione) part of each protein molecule in muscle is orientated at some external surface, and it is probable that this surface is again the surface of the fibrils, and that the glutathione-lecithin is orientated in opposite places, in order to give the reversible reactions of reduction and oxidation, during muscular contraction and relaxation.

E. GORTER.
F. GRENDEL.

Leyden.

Bigamous Hydrogen—a Protest.

NATURE is always both helpful and challenging and though these be degenerate days, in which the policeman stops duelling, as there is no organised scientific police force, some of us must answer her call and at least constitute ourselves special constables in protection of the liberties of our craft. Scientific son as I am, plus sixty years old, of Frankland, who was the first to enunciate the doctrine of valency, *upon which our entire system of structural chemistry is based*, I have been accustomed always to regard hydrogen as the most single-minded and moral of monogamists. If the story of chemistry, especially that of paraffinic chemistry, mean anything, it is that carbon and hydrogen are mutually satisfied when the carbon atom is married with four hydrogen atoms. The indifference to all external temptation of such unions is most remarkable: whether rightly or wrongly, we have, in consequence, built our entire symbolic edifice upon the assumption that hydrogen is a consistent monad.

I notice that, in the lecture, in honour of Biot, which Prof. Lowry gave recently, in Paris, upon his own work (NATURE, February 20, p. 271), he brought forward certain freak formulæ for tartaric acid, in which hydrogen figures as bigamist. I publicly protested against such aspersion by him of its character, last April, in Brussels: yet the libel is repeated. I may say, he but follows the loose example set by certain Uesanians, especially one E. N. Lewis, a Californian thermodynamiter, who has chosen to disregard the fundamental canons of chemistry—for no obvious reason other than that of indulging in premature speculation upon electrons as the cause of valency: in effect, he has but substituted pairs of dots for the chemist's single bond, thereby deluding himself, apparently, into the belief, that a love-pair of electrons may be hugged by the single hydrogen atom. The way in which the speculation is set out is open to question chemically on almost every page. To quote one case: we are told, that having painted hydrogen as electronegative, as the analogue of fluorine (!), the author had predicted that metallic hydrides would prove to have the character of salts and give hydrogen at the anode. This prediction, we are told, "has been entirely verified in the work of Bardwell (1922), who succeeded in electrolysing a melt containing calcium hydride and obtaining hydrogen at the anode, in amount corresponding to Faraday's Law" No proof has been given, that this hydrogen was not merely displaced by the alkali-metal liberated, during electrolysis, from the fused mixture of alkali-metal chlorides with the hydride used in the experiment. That a writer who belongs to the physical school should be oblivious of such possibility is astounding.

The bigamy of hydrogen is disguised by the blessed word co-ordination—which to-day covers a multitude of wild speculations. Hydrogen, like oxygen, forms co-ordination compounds, says Prof. Lowry. "The real existence of this type of co-ordination can be proved [*sic*] both by crystallographic and by chemical evidence. The X-ray analysis of ice has proved [*sic*] that each atom of hydrogen is surrounded symmetrically by four atoms of hydrogen and that each atom of oxygen is placed symmetrically between two atoms of oxygen."

I heard Sir William Bragg give his paper on ice at the Physical Society and well remember how carefully he pointed out, that the experimental evidence was in no way complete. Do we in the least know the structure of ice? Does position, as determined by X-ray analysis, settle valency? Sodium in salt has six chlorines and chlorine six sodiums surrounding it—are sodium and chlorine to be declared hexads? We are assured that they are not even combined in salt. I would add—we do not believe this, those few of us who are chemists and take some notice of laboratory facts.

As to Prof. Lowry's chemical evidence—

"The simplest chemical evidence for the co-ordination of hydrogen is to be found in potassium hydrofluoride, $KHF_2 \rightleftharpoons \overset{+}{K} + \overset{-}{HF_2}$. A complex anion is here formed by the union of two fluoride-ions and one hydrogen-ion. Since the fluoride-ions are both negatively charged and each ion carries a complete octet of electrons, there can be no direct attraction between them. Since, however, both fluoride-ions have an attraction for the positively charged hydrogen-ion, this may very well act as a link between them as in the formula $:\underset{\cdot\cdot}{\overset{\cdot\cdot}{F}}:H:\underset{\cdot\cdot}{\overset{\cdot\cdot}{F}}:$ or $\overset{-}{F}\overset{+}{H}\overset{-}{F}$, where the two fluorines are linked together by a hydrogen nucleus, in just the same way as the oxygen atoms in ice."

From beginning to end this passage is nothing but stark, unsupported and unsupportable assumption and assertion. As it is "off the rails," such speculation, however, in these days of loose thinking, is regarded as something to be worshipped and imitated. "Dragons that are but clay within and brass without" still secure adoration. As of old, they need to be burst asunder with "lumps of seethed pitch and fat and hair."

Prof. Lowry finds difficulty in "the free rotation of the molecule [of tartaric acid] about the single bond between the two central carbon atoms"—hence his device of connecting by means of hydrogen.[1] I suggest that there is no sufficient evidence that such free rotation is usual, if possible. He also speculates as to the character of the dissymmetry of camphor. On this, may I suggest, that the camphor formula which we are accustomed to use is geometrically impossible. I began my career by doubting Kekulé's formula—at its close, I take leave to question the long fashionable substitute and would even assert that the views now current upon the structure of the compounds of the polymethylene and terpene class are often fundamentally unsound and in need of revision.

Prof. Lowry's early optical work is of such perfection, that it is most unfortunate that he, of all chemists, should now indulge in these obscurantisms. The bump of judgment seems to be lacking in the modern school of chemistry—the judicial sense is nowhere to be found. Seemingly, any wild-cat speculation may be indulged in upon paper. Surely, it were time that we returned to serious work in the laboratory and that some effort were made to inculcate the principles of logic into the minds of university students. The entire system of academic teaching is fast becoming suspect: the product is not what we need in practice: it has no power of reasoning upon observation.

HENRY E. ARMSTRONG.

New Experimental Results concerning the Doublet $K\beta_1$.

IN a paper recently published (*Z. f Phys.* 33, 601, 1925) the present authors came to the conclusion that the new line β' constitutes with the line β_1 the "relativity doublet." In a letter received by the authors, Prof. Sommerfeld points out that, in his opinion, the line β' ought to be considered as a spark line or as a line of unknown origin, since $\Delta\lambda'$ according to our data is equal to 4·3 $X.U.$, whilst according to Allison's $\Delta\lambda$ for M_5 is equal to 0·56 $X.U.$ The value given by Allison may be verified with the aid of the data for the wave-lengths $L\beta_3$ and $L\beta_4$ which are emitted, when the transition of electrons takes place between the levels M_3 or M_4 and the level L_2, while the transition of electrons from the same levels M_3 and M_4 to the level K gives rise to the lines $K\beta_1$ and $K\beta'$. Accordingly we obtain for $\Delta\nu/R$ from the data for the L series for M_5 the value 1·63, and from Allison's data - 1·27.

The agreement is quite satisfactory. However, we cannot act similarly in our case, as the data for the L series for manganese and the neighbouring elements are not known. Nevertheless, Sommerfeld's point of view may be subjected to another test. In accordance with Wentzel's theory the presence of the spark lines in the part of the spectrum close to the line $K\beta_1$ is due to the fact that the atoms of elements from copper downwards, possessing an uncompleted group M, readily pick up an additional electron and retain it on one of the M levels. Consequently the levels in the corresponding atoms ought to be displaced, and therefore a displacement of the lines of the K series must be expected.

What is the actual process by means of which the catching of an additional electron in the uncompleted group takes place? This may be realised in different ways. For example, the electron striking the anticathode may under favourable conditions penetrate inside the atom and be kept there in the group M, or one of the electrons ejected from the level K may also be stopped in the group M. There are undoubtedly other possible cases, when the electrons may be caught in the uncompleted group. Therefore the existence of atoms of two different kinds seems to be probable: the normal atoms and the atoms charged with an additional electron in the uncompleted M group, by means of various processes.

It is obvious that the atoms in which the additional electron has been ejected from the K level possess the greatest probability of the emission of the line $K\beta'$. If this process actually takes place, we are justified in expecting to find in the absorption spectrum the absorption lines of the wave-lengths equal to $K\beta'$, or close to it. The effect of the absorption may be easily estimated. The relative intensities of the lines of the K series are 100, 50, 35, 17·5, and 15 (Siegbahn; Seljakow and Krasnikow). Hence, it may be stated that the probability of the transition of electrons from the M level to the K level will be roughly 8 per cent. of the probability of the ejection of electrons from the K level. Therefore an electron must be ejected from the K level to one of the M levels not less than 8 times in 100, in other cases being expelled outside the atom. From Glocker's formula it may be calculated that a line in the absorption band, after passing through a sheet of iron or manganese 0·02 mm. thick, will be weakened 1000 times more than any line out of the absorption band under the same conditions. Then one can expect that the lines $K\beta_1$ and $K\beta'$ from manganese and iron, after passing through sheets of manganese and iron 0·02 mm. thick, will suffer weakening to a markedly different degree, or at least that a new absorption line will appear close to the line $K\beta'$.

The experiment gives opposite results: namely, the ratio of the intensities of the lines $K\beta_1$ and $K\beta'$ in the absorption spectrum remains actually the same as in the emission spectrum. There is also no trace of any absorption line in the region we are interested in. Moreover, it was of some interest to know if the line $K\beta'$ would appear at the critical voltage or not. For that purpose the constant voltage was supplied by a Siemens machine of 10,000 V. Thus the voltage did not exceed the critical value for manganese by more than 200-300 volts. Experiments have shown that, in the presence of the line $K\beta_1$, the line $K\beta'$ was always present, and vice versa, in the absence of the first line the second was also absent. The ratio of the intensities remained unaltered and equal to that observed at high voltages.

On the strength of these experiments combined we are led to conclude that the level from which the transition of an electron gives rise to the line $K\beta'$, may be considered as a normal, and hence the combination of the lines $K\beta_1$ and $K\beta'$ is a "relativity doublet." Ray, Ray and Siegbahn (*Phil. Mag.* 1, 1924, and *Phys. Ber.*, 1925) have shown that the law $\Delta\lambda = \text{const.}$ does not hold for the "relativity doublets" in the region of elements, where, according to Bohr, the reconstruction of the inner electronic groups takes place. In these regions $\Delta\lambda$ shows a sharp maximum. A similar phenomenon, in an even more striking form, may be expected in the case of $\Delta\lambda$ of the doublet $K\beta_1$, as exactly the same group, which is in a state of reconstruction, gives rise to the lines of the doublet.

[1] In discussing the anomalous rotatory dispersive power of solution of tartaric acid, in 1913, Dr. E. E. Walker and I suggested alternative formulæ (*R. Soc. Proc.*, 88, 388). We need to know if any change in real acidity take place as the acid changes. Perhaps, as crystal, it may be the dicarboxy-acid and pass over in solution into the monocarboxy-maleic (phthalic) form. Prof. Lowry puts chemical considerations aside.

The Fluorescence of Mercury Vapour.

In the course of the study on the band absorption and fluorescence of mercury vapour I have obtained some results, which partly complete but partly contradict former experiments In the present experiments special care has been taken to maintain the mercury vapour at precisely definite conditions.

Wood (*Proc. Roy. Soc.*, 99, 362, 1921) and Wood and van der Lingen (*Astrophys. Journ*, 54, 149, 1921) have found that the fluorescence of mercury vapour cannot be excited in quiescent vapour, but only in vapour which is being distilled from the liquid metal at a temperature of 150° C. or more. These authors have arrived at this conclusion as the result of experiments made with several exhausted quartz vessels containing mercury. These vessels were heated and illuminated by an aluminium spark. The fluorescence occurred only in the case when the distillation or a stronger evaporation took place, namely, when a part of the vessel was cooled by an air blast or when the temperature of the entire vessel was rising. If the temperature remained constant for a short time or fell, the effect disappeared altogether.

My first experiments upon this subject were made with a quartz Dewar-flask specially designed for absorption measurements. The flask, carefully cleaned and dried by heating, contained between its walls a certain amount of pure liquid mercury It was connected with a constantly working mercury-vapour pump. The vessel was heated in an electric oven and the fluorescence excited by a mercury arc lamp or by condensed sparks with electrodes of aluminium, cadmium and zinc. When the temperature of the entire vessel was kept constant at about 155° C. or higher, green fluorescence limited to the beam of the exciting light was definitely observable. With increasing temperature the fluorescence became stronger. When the temperature fell, the fluorescence got gradually fainter and disappeared only at about 155° C., which is not in agreement with Wood's experiments referred to above. Moreover, by a local cooling of the wall of the vessel by means of an air blast or water, the intensity of fluorescence diminished with diminishing vapour density, instead of rising as reported by Wood.

These experiments were, however, not considered convincing, since in the vessel connected with the pumps a distillation, weak as it might be, could possibly take place. In order to avoid this difficulty, some experiments with sealed vessels were performed. Two quartz tubes provided with quartz plates at the ends were used successively Each tube containing a few drops of mercury was heated in an electric furnace closed by quartz windows; the temperature was measured at three different places by means of thermopiles fastened to the walls of the tube. The fluorescence radiation excited by an aluminium spark was observed visually and photographically. The fluorescence spectrum was taken with a quartz as well as a glass spectrograph The results obtained in these experiments fully confirm previous ones. The intensity of fluorescence remains unchanged if the entire tube is kept at constant temperature, *i.e.* when distillation and stronger evaporation—as by rising temperature—are avoided. No increase of the fluorescent radiation results from local cooling of the vessel.

The total intensity of the visible fluorescence in saturated mercury vapour as well as that of different bands and lines in the visible and ultra-violet part of the spectrum seems to be, for a given exciting light, a function of the temperature only.

In the spectrum of the fluorescence light of mercury vapour excited by an aluminium spark, besides the bands and lines observed by Wood and van der Lingen (*loc. cit*), the line 4358 Å U. was found This line is well seen on the continuous ground of the visible band. It appears at about 200° C. as a very faint line, gets stronger with rising temperature, and reaches the maximum at 230° C.-270° C, slowly declining at still higher temperatures; at 345° C. it is scarcely seen. In connexion with the line 4358 Å.U ($2p_2$-$2s$) the behaviour of the line 2537 Å.U. ($1S$-$2p_2$) in the mercury fluorescence spectrum excited by an aluminium spark may be worth mentioning. The latter appears at about 130° C, its intensity grows with the temperature, reaches a maximum value at about 230° C. and then rapidly decreases and vanishes at about 260° C.

Power (*Phys Rev.*, 26, 761, 1925) and Kapuściński (Nature, 116, 863, 1925) have observed in the fluorescence spectrum of cadmium vapour excited by some sparks, different from those of cadmium, the line $2p_2$-$2s$ analogous to the mercury line 4358 Å U. They have observed also two other lines $2p_1$-$2s$ and $2p_3$-$2s$. No trace of the corresponding mercury lines 5461 Å.U. ($2p_1$-$2s$) and 4047 Å.U. ($2p_3$-$2s$) could be found in these experiments

A detailed account of these experiments will be published elsewhere.

Alternating Intensities in Band Lines.

Bands in the spectra of neutral and ionised nitrogen show unexplained alternating intensities, and the bands of helium are best interpreted if one assumes that only half the lines are observed, the alternate lines being not merely weak but missing altogether (Mecke, *Zeits. f Phys.* 26, 227, 1925; 31, 709, 1925) A similar effect seems to be present in oxygen, although the interpretation is less certain. All these molecules are symmetrical, composed of two like atoms. I wish to suggest that the alternations may be connected with the well-known difficulty of assigning the proper period in quantising the rotation of a symmetrical system (Ehrenfest and Tolman, *Phys. Rev.* 24, 287, 1924).

If a dumbbell rotates about the perpendicular bisector of its axis, it returns after half a revolution to a state which cannot be told from the initial state; the place of each end of the dumbbell is taken by the other end. If we wished to quantise the rotation, we might think that the right period for integrating pdq was this half rotation. Then, using p_ϕ, the angular momentum, and ϕ, the azimuth, we should have $\int_0^\pi p_\phi d\phi = nh$, $p_\phi = nh/\pi$. That is, the angular momentum of successive allowed states would differ by h/π, twice the normal amount of $h/2\pi$, and we might say that every other level was missing. It seems physically most likely that there would be some continuous kind of transition from this case to the case of a non-symmetrical rotator, where all the states are present, and the only possible way would be to have the missing levels gradually appear with increasing dissymmetry of the rotator, first with very small *a priori* probability, and finally assuming their normal *a priori* probability in a sufficiently assymmetrical rotator. The extreme case of symmetry might actually occur in the helium molecule, the intermediate state in the nitrogen.
